ABSTRACT: The growing concerns over desertification have spurred research into technologies aimed at acquiring water from nontraditional sources such as dew, fog, and water vapor. Some of the most promising developments have focused on improving designs to collect water from fog. However, the absence of a shared framework to predict, measure, and compare the water collection efficiencies of new prototypes is becoming a major obstacle to progress in the field. We address this problem by providing a general theory to design efficient fog collectors as well as a concrete experimental protocol to furnish our theory with all the

necessary parameters to quantify the effective water collection efficiency. We show in particular that multilayer collectors are required for high fog collection efficiency and that all efficient designs are found within a narrow range of mesh porosity. We support our conclusions with measurements on simple multilayer harp collectors.

KEYWORDS: fluid mechanics, fog collector, harp design, porous media, water collection efficiency

1. INTRODUCTION

Many regions of the world experience chronic water shortages and their associated impacts on human health and economic growth. This crisis has spurred research for novel technologies to exploit alternative water sources such as fog, 2,3 dew, 4-6 and even water vapor. Where the conditions are favorable, fog stands out as one of the most attractive water sources because fogwater can, in principle, be collected in large amounts without any input of energy. Accordingly, a large body of work has focused on the design of efficient fog collectors. Fog collection is usually achieved with fine meshes exposed to the incoming fog stream. The minuscule fog droplets intercepted by the threads accumulate until they reach a critical size at which point the force of gravity overcomes the surface tension forces allowing drops to slide down the collector's surface to reach the gutter at its base.

The central design challenge for efficient fog collection involves funding the optimal balance between two physical processes that have opposite requirements. ¹⁹ On the one hand, fog collecting meshes cannot be very dense or present a major obstacle to the flow of air; otherwise, the incoming fog stream will simply bypass the structure laterally. On the other hand, fog droplets can be intercepted only if they encounter a mesh element while they transit through the collector. Therefore, meshes that are either too dense or too sparse make poor collectors. A related issue for fog collectors is clogging of the mesh by the water droplets that have been captured, thus making the collector less permeable to the incoming fog and

reducing the overall water collection efficiency. ¹¹ Material scientists have sought to alleviate the problem of clogging by making structural changes to the mesh such as using harp designs ^{17,20} or branched patterns ^{21,22} instead of using the standard criss-crossing meshes that tend to trap water drops. Other material science contributions have explored modifications of the collecting surfaces to allow intercepted droplets to coalesce and move quickly under the action of gravity. ^{23–25} In particular, modifications of the contact angle hysteresis can reduce the critical size a drop needs to reach before it is freed from the mesh. ¹¹ However, many of these possible improvements will have to be scaled to realistic sizes (>1 m²) and produced at a competitive price (less than \$25 USD per m²) ²⁶ before they can be used in the field.

An alternative avenue to improve the performance of fog collectors arises from observations of the bromeliad *Tillandsia landbeckii*, a plant that relies almost exclusively on fog to fulfill its water needs.^{27–29} *Tillandsia* forms large stands on the fogprone coast of the Atacama Desert of Chile. These stands are striking in that the plants self-organize into bands orthogonal to the flow of fog (Figure 1A), thus allowing each plant direct

(B) Close-up of $Tillandsia\ landbeckii$ showing the dense three-dimensional array of leaves. (C) Hydrophilic scale-like trichomes covering the leaves and branches of Tillandsia. (D) Prototype of a 1 m × 1 m multilayer fog collector with a mesh solidity s=0.3 per layer and N=4 layers. (E) Top view of the air flow around a fog collector. The typical collector length is 1 m $\leq l \leq 10$ m. Streamlines are drawn based on wind tunnel experiments of Ito and Garry, with a square mesh gauze of solidity 0.63 at $Re=10^5$ based on the collector size. (F) Close-up of the air flow around the section of two cylindrical threads of the collector. The diameter of the threads $d \simeq 150-160~\mu m$ for the collector shown in (D) and the experiments discussed below. $d_{\infty}(r)$ represents the span of streamlines whose droplets of radius r will be intercepted by the thread directly downstream. The top and bottom halves of the diagram show the interception of the small and large droplets, respectively; dashed lines indicate approximate trajectories of intercepted droplets. Streamlines are based on Gordon's simulations d at d and d are d based on the thread diameter.

access to the fog stream. Moreover, the leaves and stems of *Tillandsia* are reduced to thin filamentous structures organized into a three-dimensional mesh, a unique feature among bromeliads (Figure 1B). Finally, a dense layer of hydrophilic trichomes covers the plant surfaces (Figure 1C). Three aerodynamically significant length scales emerge from observations of *Tillandsia*: the smallest length scale is that of the trichomes ($\sim 100~\mu m$) involved in intercepting fog droplets, the intermediate length scale is the characteristic pore size between the leaves ($\sim 1~mm$) through which the fog must filter, and the largest length scale is the self-organization of *Tillandsia* plants into fog collecting stands ($\geq 1~m$). These observations indicate that 3-D structures, with appropriately selected length scales, can be efficient at collecting fog.

Inspired by *Tillandsia landbeckii*, we investigated the potential of multilayer fog harvesters for resolving the issues associated with single-layer collectors and improving the water collection efficiency. Although the collectors we analyze and test do not incorporate any specific microstructure of the *Tillandsia* plant, their 3-D design adopts the characteristic length scales observed in these plants (Figures 1D–F). Despite having been field tested more than 50 years ago, ³⁰ with the exception of one recent study, ³¹ the performance of multilayer collectors has not been studied theoretically. To this date, it is still unclear whether broadly applicable design principles exist. Here, we formalize the fundamental trade-off associated with the capture of fog with multilayer collectors and demonstrate that simple design rules can guarantee nearly optimal fog collection efficiency.

2. THEORY

Total Water Collection Efficiency η_{tot} . To formalize the performance of fog collectors, we define, as others have done before, ^{19,31,34} the total water collection efficiency (η_{tot}) as the water flux coming out of the collector's gutter for each unit of

collector area $(J, g s^{-1} m^{-2})$ divided by the liquid water flux of the unperturbed fog upstream of the collector:

$$\eta_{\text{tot}} = \frac{J}{\text{LWC} \cdot u_{\infty}} \tag{1}$$

where LWC is the liquid water content of fog and u_{∞} is the velocity of the unperturbed fog flow, which we assume to be orthogonal to the surface of the collector. A typical range for the LWC is 0.2–0.5 g m⁻³, while the characteristic fog velocity is 2–5 m s⁻¹. ^{34–36}

It is convenient to define η_{tot} in geometrical terms by considering how a fog droplet upstream of the collector can ultimately be found in the flux of water I coming out of the collector's gutter. The initial stages of collection operate at different length scales (Figures 1E,F). First, we consider what happens at the scale of the entire fog collector (Figure 1E), where the characteristic Reynolds number based on the collector size ($l \sim 1-10$ m) and unperturbed air velocity (u_{∞} $\sim 5 \text{ m s}^{-1}$) is $Re = u_{\infty}l/\nu \sim 10^6 \ (\nu = 1.4 \times 10^{-5} \text{ m}^2 \text{ s}^{-1} \text{ is the}$ kinematic viscosity of air). Incoming fog droplets are part of an airstream that must filter through the collector if the droplets are to be captured. Because the collector is an obstacle to the free flow of the airstream, a fraction of the incoming fog will simply bypass it (Figure 1E). The filtered fraction (φ) can be quantified geometrically as the ratio of two areas: $\varphi = A_{\infty}/A$, where A_{∞} is the area of the incoming fog flow that will filter through a collector of frontal area A. In the specific case of a square collector (Figures 1D,E), the filtered fraction is $\varphi =$ $(l_{\infty}/l)^2$.

The second collection stage takes place at a microscopic scale and pertains to the droplets transiting through the collector. Of these filtered droplets, only a subset will be on a trajectory that ensures collision with one of the collector elements (Figure 1F). For any given layer of the collector, the probability that a droplet collides with a thread is given by $(d_{\infty}(r)/d)s$, where the ratio $d_{\infty}(r)/d$ represents the efficiency

of inertial impaction for a droplet of radius r (Figure 1F) and s is the solid fraction, or solidity, of the layer (s=d/h for our harp design). Conversely, the probability that a droplet captured by a layer has a radius in the interval [a, b] is $s \int_a^b (d_\infty(r)/d) f(r) dr$, where f(r) is the probability density function for fog droplet sizes. Given that the mass of water provided by a droplet scales with r^3 , the relative contribution of droplets to the capture efficiency is $\int_a^b (d_\infty(r)/d) m(r) dr$, where

$$\int_{a}^{b} m(r) dr = \frac{\int_{a}^{b} r^{3} f(r) dr}{\int_{0}^{\infty} r^{3} f(r) dr}$$
(2)

 $\int_{a}^{b} m(r) dr$ is the mass fraction of liquid water contained in droplets with radii in the interval [a, b].³⁷

Finally, to these two processes, we should add the drainage efficiency $(\eta_{\rm drain})$. The drainage efficiency may be reduced by re-entrainment of captured droplets under high wind conditions, 30 evaporative losses from the liquid water accumulated on the collector, and potential leaks in the gutter and pipe leading to the collector's tank.

In the case of a single-layer collector, the three processes detailed above lead to the total water collection efficiency

$$\eta_{\text{tot}} = \eta_{\text{ACE}} \eta_{\text{capt}} \eta_{\text{drain}} = \underbrace{\left[\frac{A_{\infty} s}{A}\right]}_{\eta_{\text{ACE}}} \underbrace{\left[\int_{0}^{\infty} \frac{d_{\infty}(r)}{d} m(r) \, dr\right]}_{\eta_{\text{capt}}} \eta_{\text{drain}}$$

where $\eta_{\rm ACE}$ is the aerodynamic collection efficiency (ACE) introduced by Rivera. ¹⁹ When considering a collector with N layers, the total collection efficiency takes the form

$$\eta_{\text{tot}} = \frac{A_{\infty}}{A} \left[1 - \underbrace{\int_{0}^{\infty} \left(1 - \frac{d_{\infty}(r)}{d} s \right)^{N} m(r) \, dr}_{\text{lost mass fraction}} \right] \eta_{\text{drain}}$$
(4)

where the term $(1 - (d_{\infty}(r)/d)s)^N$ is the probability that a drop of radius r traverses the N layers of the collector without being intercepted (see also Demoz et al.³⁸). Consequently, the integral represents the mass fraction of liquid water that filtered through the collector without being intercepted.

Three tacit assumptions were made to arrive at eq 4. These assumptions are listed here to define clearly the range of validity of our results. First, we assume that the incoming airflow both far-field and just upstream of the collector is orthogonal to the collector's surface. We justify this assumption because the optimum fog collectors are quite porous, with ~80% of the incoming fog flow passing through the collector. In this regime, the air velocity has a negligible component tangential to the collector surface (see below), so the interaction of the airflow with the collector filaments does not depend on position within the collector. Second, we assume that $d_{\infty}(r)/d$ is constant at all locations within the collector. This assumption implies a uniform mesh such as the harps under consideration but would have to be modified for meshes made of intersecting weft and warp threads and potentially differing in their size and shape. Third, in deriving the lost mass fraction, we make the hypothesis that the distance between the layers is sufficiently large to allow the fog stream to regain uniformity before reaching the next layer. As

we will show below, the optimal interlayer spacing ranges between 6 and 9 mm, which is at least 40 times greater than the characteristic thickness of the layers in our prototypes.

Maximizing η_{tot} . Because eqs 3 and 4 are geometrical definitions of η_{tot} , they are valid irrespective of the fluid mechanics model that might be developed to quantify the collection efficiency. Ideally, we would like to design the collector such that all steps in the harvesting of fog droplets are maximized to achieve a total water collection efficiency approaching unity. Our goal in this section is to establish that η_{ACE} is the only component of η_{tot} that involves some fundamental design trade-off.

We begin with the drainage efficiency, η_{drain} , which is included in eqs 3 and 4 to take into account the possibility that captured fog droplets are either re-entrained by the airstream or otherwise lost due to leaks in the system. Although leaks need to be taken into account in any implementation of a fog collector, they are outside the scope of our fluid mechanical analysis, but re-entrainment is not, and hence needs to be considered more carefully. Two ways to eliminate reentrainment are (i) the use of multilayer collectors to allow re-entrained drops to be recaptured by a layer farther downstream³⁰ and (ii) the reduction in the size of the drops clinging to the collector surface so that the drag on these drops does not exceed the critical value that would cause them to detach. These design requirements are in fact among those put forward to optimize the other aspects of the collection process; therefore, the drainage efficiency will be optimized de facto. In what follows, we set $\eta_{\text{drain}} = 1$ and focus on the other terms of eqs 3 and 4.

At the operational Re number of fog collectors, the ratio $d_{\infty}(r)/d$ reflects a deposition mechanism by inertial impaction. For a droplet of radius r, the efficiency of impaction follows the relation 20,39

$$\frac{d_{\infty}(r)}{d} = \frac{Stk}{Stk + \pi/2} \tag{5}$$

where $Stk = (2\rho_w r^2 u)/(9\mu d)$ is the Stokes number, ρ_w is the density of liquid water, u is the velocity of the air stream, μ is the dynamic viscosity of air, and d is the diameter of the thread. This efficiency increases with increasing Stk; however, we note from the definition of *Stk* that the thread diameter *d* is the only parameter that can be tuned in the context of a passive fog collector. Because Stk increases for decreasing d, the width of the elements on which droplets are impacted should be reduced to a minimum. More precisely, Labbé and coworkers²⁰ demonstrated that the size to be considered is the diameter of the thread with the water film or drops covering it. The reduction in the size of the collecting elements can be done at constant solidity and without compromising other steps of the fog collection process. Consequently, the geometrical ratio $d_{\infty}(r)/d$ can be made as close to unity as one desires, although maximizing $d_{\infty}(r)/d$ for all droplet size classes is unwarranted since the smallest droplets are the most challenging to capture, and yet they represent a vanishingly small fraction of the total LWC of fog.

In what follows, we consider a small operating diameter for the collecting elements so that $d_\infty \to d$. In this limit, eq 4 becomes

$$\lim_{d_{\infty} \to d} \eta_{\text{tot}} = \eta_{\text{ACE}} = \underbrace{\frac{A_{\infty}}{A}}_{\varphi} \underbrace{\left[(1 - (1 - s)^{N}) \right]}_{\chi}$$
(6)

This equation captures in the most general form the aerodynamic collection efficiency (η_{ACE}) ; that is, the fraction of droplets in an unperturbed upstream flow of area A that are both filtered by (φ) , and incident to (χ) , the elements of a multilayer collector. The ACE is of special significance because it encapsulates the fundamental trade-off in the design of efficient fog collectors. While the incident fraction χ increases with increasing solidity s and with increasing number of layers N, the same parameter changes reduce the collector porosity and therefore decrease the filtered fraction φ .

Fluid Mechanical Calculation of A_{∞}/A . Determining ACE for a specific collector involves finding the ratio $\varphi = A_{\infty}/A$. A by using the design parameters of the collector, such as the solid fraction of the individual mesh layers and the total number of layers. We first note that incompressibility of the flow together with mass conservation implies $Au = A_{\infty}u_{\infty}$ (Figure 1E). Therefore, the geometrical definition of the filtered fraction is also a statement about the ratio between the mean velocity across the collector mesh and the velocity far upstream of the collector:

$$\varphi = \frac{A_{\infty}}{A} = \frac{u}{u_{\infty}} \tag{7}$$

We follow the many earlier studies of fluid flow through and around porous structures that equate two alternative definitions of the pressure drop across the porous material—the first one at the scale of the porous medium and the second one at the scale of the far-field flow. At the microscopic scale, the pressure drop is

$$\Delta P = k \frac{\rho_{\rm air} u^2}{2} \tag{8}$$

where $\rho_{\rm air}$ is the density of air and k is the pressure drop coefficient for the flow of an inviscid fluid through a porous medium. This equation arises naturally from Bernoulli's principle.³⁷ As we shall see, since k is typically not constant over a very large range of velocities, the pressure drop coefficient is necessarily expressed in terms of the solid fraction of the medium and the Reynolds number. At the scale of the entire collector, the pressure drop across the mesh is also related to the drag coefficient $C_{\rm D}$

$$\Delta P = \frac{F_{\rm D}}{A} = C_{\rm D} \frac{\rho_{\rm air} u_{\infty}^2}{2} \tag{9}$$

because the drag force $F_{\rm D}$ per unit area on the screen must equal the pressure drop. Equation 9 represents the so-called "form drag" and is valid for blunt objects at high Reynolds numbers, which is the case for fog collectors.⁴⁰ Equating the two pressure drops, we obtain the filtered fraction

$$\varphi = \frac{A_{\infty}}{A} = \frac{u}{u_{\infty}} = \sqrt{\frac{C_{\rm D}}{k}} \tag{10}$$

This relation has been used in its various forms by Taylor,⁴¹ Koo and James,⁴² and Steiros and Hultmark,⁴³ among many others.

There is no consensus on how to express the drag coefficient $C_{\rm D}$ and the pressure drop coefficient k in terms of the design parameters of the collector mesh. To our knowledge, the most recent and most complete treatment is due to Steiros and Hultmark⁴³ (later termed Steiros2018), who extended the earlier work of Koo and James⁴² by including the so-called

"base suction" and thus obtained accurate predictions of the drag coefficient over the entire range of solid fractions. According to their model, the drag and pressure drop coefficients are

$$C_{\rm D} = \frac{4}{3} \frac{(1-\varphi)(2+\varphi)}{(2-\varphi)} \tag{11}$$

$$k = \left(\frac{1}{(1-s)^2} - 1\right) - \frac{4}{3} \frac{(1-\varphi)^3}{\varphi^2 (2-\varphi)^2}$$
 (12)

Substitution of these two relations in eq 10 gives an implicit relation for the filtered fraction as a function of the solidity. Finally, because k is the coefficient for the pressure drop across one layer of the collector, the total pressure drop across multiple layers is obtained by multiplying k by the number of layers in the collector. The additivity of the pressure drop coefficient was shown by Eckert and Pflüger⁴⁴ when the distance between the screens is sufficiently large, and Idel'Cik showed that the pressure drop across multiple layers is additive as long as the distance of separation between the layers exceeds 15 times the size of the threads (ref 45, page 291).

3. RESULTS AND DISCUSSION

To maximize the overall collection efficiency, we must seek a high filtered fraction (φ) and a high incident fraction (χ) . However, these quantities are maximized at opposite ranges of the parameters s and N (Figures 2A,B). The results obtained in the previous section allow us to calculate the maximum ACE found at some intermediate values of these parameters.

As can be noted in Figure 2B, the incident fraction χ depends very nonlinearly on N which, at a glance, establishes the notable advantage offered by multilayer designs. In a singlelayer collector, the incident fraction cannot be maximized to unity, as this would imply complete obstruction of the mesh and thus no airflow through the collector. The use of several layers decouples, at least partially, the fluid mechanical processes behind the filtered fraction and the incident fraction. It is therefore possible to design the collector such that nearly all upstream droplets are on a collision course with one of the collector elements while maintaining the solidity significantly below unity (Figure 2B). Even for a relatively modest five-layer collector, a solidity as low as 0.5 can already guarantee a near maximal incident fraction (Figure 2B). The possibility of greatly increasing the incident fraction for intermediate solidity values is the reason why multilayer collectors achieve higher efficiencies. Moreover, because the equation for the incident fraction is purely geometrical, there is no doubt about the general validity of this conclusion.

Computation of the aerodynamic collection efficiency $\eta_{ACE} = \varphi \chi$ for a broad parameter range indicates that it reaches a maximum of 49% for N=10 (Figure 2C). In contrast, single-layer collectors are confined to the line N=1 and can reach a maximal ACE of only 30% at an operational solidity slightly above 0.5. Increasing the number of layers beyond 10 increases the ACE further, with the theoretical possibility of reaching an ACE of unity for very large N (Figure 2D). This limiting behavior raises the question of how many layers should be used in practice. An answer emerges when considering the contribution to the total ACE made by each new layer (Figure 2D). Beyond N=5, the relative increase in ACE becomes vanishingly small. Therefore, considerations about the most efficient use of available materials would suggest that the

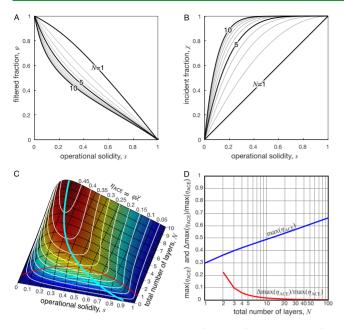

Figure 2. Aerodynamic collection efficiency for multilayer fog collectors. (A) Filtered fraction predicted from the Steiros2018 model (eqs 10–12). (B) Incident fraction computed from geometrical considerations (eq 6, second term on the rhs). (C) ACE Ridge—a 3D representation of ACE as a function of the two control parameters s and N. A maximum ACE of 0.49 is observed for 10 layers, each with an operating solidity of 0.17. The blue curve marks the subspace where $\eta_{\rm ACE}$ is maximized at constant N. Single-layer collectors are confined to the line N=1 and have an ACE below 0.3 (note: we have treated N as a continuous variable for the purposes of illustration). (D) Maximal ACE as a function of N (plotted on a log scale). Although $\max(\eta_{\rm ACE})$ increases with increasing N, the relative ACE increase, Δ max($\eta_{\rm ACE}$)/max($\eta_{\rm ACE}$), becomes small for N > 5 and negligible for N > 10.

number of layers should be limited to \sim 5, at least in the limit where $d_{\infty} \rightarrow d$.

As indicated in the Theory section, the Steiros2018 model is one of many models, published over a period of 80 years, that provide a fluid mechanical formulation for the filtered fraction (Supporting Information). The functional form and the asymptotic behavior of the filtered fraction predicted by alternative theories vary substantially (Figure 3A). In that respect, the Glauert1932 model⁴⁶ and the Rivera2011 model¹⁹ represent two extreme behaviors, while the Steiros2018 model⁴³ adopted here and its precursor, the Koo1973 model,⁴² are intermediate for the limiting behavior of φ as $s \rightarrow 0$. The prediction of the models for small solidity is especially important in the context of multilayer collectors since their maximal ACE is attained for solid fractions below 0.3 (Figure 3B).

A comparative analysis of the design space for these models is also informative. Notably, although the models disagree on the maximum $\eta_{\rm ACE}$ that can be achieved for a given N, their respective ACE ridges follow similar arcs in design space (Figure 3B). Specifically, they all go through a small target area (0.25 < s < 0.35, N = 4,5) where the multilayer collectors achieve an efficiency ~40% better than the most efficient single-layer collectors. The quantitative agreement between the models shows the robustness of the efficiency optimization in design space (see also Regalado and Ritter³¹ for qualitatively similar results). Interestingly, the subspace where $\eta_{\rm ACE}$ is locally maximized follows closely curves of constant filtered

fraction for all four models (Figure S1). Therefore, the improved aerodynamic collection efficiency of multilayer fog collectors comes almost exclusively from improvements in the incident fraction as new layers are added to the system.

Because the models differ substantially in their predicted maximum ACE (from 34% to 63% for a 10-layer collector), we undertook a series of experimental observations to quantify the efficiency of multilayer collectors. As noted above, the equation for η_{ACE} is first and foremost a statement about two geometrical ratios: the area ratio associated with the filtered fraction and the solidity s of the mesh (ratio of obstructed area over the total area of one collector layer). To assess the ACE, we developed a wind tunnel to produce realistic fog conditions in the laboratory (Figure 4A and Movie S1). Experimenting with a four-layer harp collector (l = 100 mm, h = 2 mm, d =0.150 mm), we found an operating solidity of s = 0.17 (Figures 4B,C), giving an incident fraction of $\chi = 1 - (1 - s)^4 = 0.53$. Integrating the flow field, we arrived at a filtered fraction of $\varphi_{\rm obs} = (l_{\infty}/l)^2 = 0.81 \pm 0.016$ (Figures 4D,E). Based on the measured incident and filtered fractions, the aerodynamics collection efficiency is $\eta_{ACE} = \varphi \chi = 43\%$, which exceeds slightly the value of 37% predicted by the Steiros2018 model (Figure 2C). The discrepancy arises in part because of the impossibility of measuring the flow field within 10 mm of the collector's surface with our current experimental setup. The truncated velocity field leads to a slight overestimate of the filtered fraction (Table S1 and Figure S2). A more complete reconstruction of the velocity field could be achieved with other flow visualization methods such as the smoke-wire technique.47

Given the care needed to measure ACE, it might be asked why it should be preferred as a performance standard over the total water collection efficiency, η_{tot} , as defined in eq 1. The reason is that although eq 1 appears tractable at first sight, a more detailed analysis (eq 4) reveals that $\eta_{\rm tot}$ involves the lost mass fraction, $\int_{0}^{\infty} (1 - s \, d_{\infty}(r)/d)^{N} \, m(r) \, dr$, where the terms $d_{\infty}(r)/d$ and m(r) both depend on the radius of the droplets in the incoming fog. Notably, these two terms give, together, a scaling on the order of r^5 (see the Theory section). Therefore, unless the probability density function for the droplet sizes, f(r), is characterized precisely, the total water collection efficiencies are impossible to compare. In fact, it could be argued that due to its very nonlinear dependence on r, $\eta_{\rm tot}$ is virtually useless as a metric for efficiency because of its great sensitivity to the presence of rare but large droplets. In contrast, ACE is what is left of η_{tot} when factors affected by the droplet size distribution of fog are eliminated (eq 6). Moreover, ACE captures the fundamental trade-off for fog collection. Therefore, in an effort to increase the repeatability and portability of future research in fog collection, we propose the geometrical measurement of ACE as a potential standard for the field (Figure S3).

As a final validation of the performance of multilayer collectors, we compare their yield with that of the standard fog collecting medium—two plies of Raschel mesh ("dry" solidity s = 0.6)⁴⁸ without spacing between them and thus approximating a single-layer collector. As expected, the yield of the multilayer harps greatly exceeds that of the Raschel standard (Figure 5). Notably, even a single harp layer offers a slightly better yield than the two-ply Raschel mesh (Figure 5B). The poor performance of the Raschel mesh under well-defined laboratory conditions is explained by the fact that the two-ply

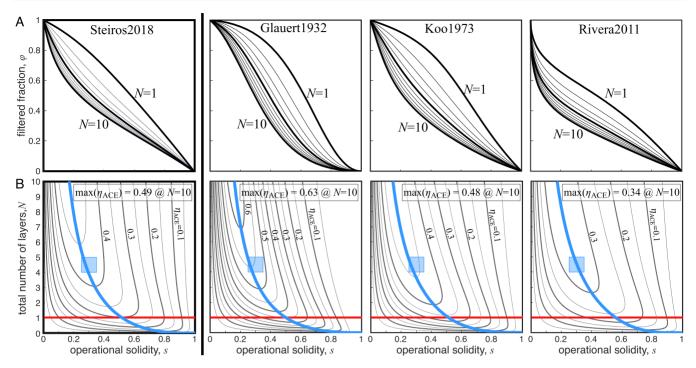

Figure 3. Comparative analysis of the ACE ridge. (A) The filtered fraction predicted by four fluid mechanics models. Note the model-dependent form of the asymptotic behavior of $\varphi(s)$ as $s \to 0$. (B) Design space for the models listed in (A). The blue curve marks the subspace within which ACE is locally maximized at constant N. The blue square is the suggested target design. The red line at N = 1 is the design space for single-layer collectors.

mesh exceeds greatly the optimal operational solidity ($s_{Raschel} \simeq 0.7 \text{ vs } s_{opt} \simeq 0.5$). While the multiharp designs outperform single-layer designs for all N, these collectors lose some of their yield for $N \geq 6$ (Figure 5B), a result that is not predicted from the design space. This efficiency loss probably arises because of the increasing boundary layer that develops in the vicinity of the collector frame. In the case of a 10-layer collector, the frame depth exceeds 50 mm while the open area for filtration

remains 100 mm \times 100 mm. In other words, for large N, the collector depth is such that the collector forms an increasingly long tube through which the fog stream must flow. Despite this limitation, the five-layer harp offers a 4-fold increase in yield (Figure 5B). These results were confirmed in field experiments with the four-layer harp prototype shown in Figure 1D. During a period of low fog, the prototype collected 4.3 L day⁻¹ m⁻² while the two-ply Raschel mesh collected only 1 L day⁻¹ m⁻² (Figure 5C).

4. CONCLUSIONS

In this paper, we have presented designs for optimally efficient passive fog collectors by focusing on a geometrical relation (eq 6) known as the aerodynamic collection efficiency (ACE). As we have shown, the maximal values of ACE are achieved only through the use of multilayer collectors whose efficiency can exceed by 40% that of the best single-layer collectors. The analysis shows that taking into account the most effective use of materials, the optimal fog collector has N=4,5 layers and operating solidity $s=0.3\pm0.05$, assuming that the *operating* thread diameter is sufficiently small to maximize inertial impaction of fog droplets. These conclusions were validated experimentally for multilayer harp collectors. When optimized, the latter can collect as much as 4 times that collected by the standard two-ply Raschel mesh, both under laboratory and field conditions.

5. EXPERIMENTAL SECTION

Collector Design. Multilayer collectors were built by using fast prototyping tools. By use of a laser cutter (Ready Cut), square plexiglass frames with a 100 mm \times 100 mm central open area were fabricated. Evenly spaced notches (typical spacing: 1 mm $\leq h \leq$ 2 mm) were made in the upper and lower edges of the frame to hold polyethylene monofilaments ($d = 150-160~\mu m$) into a vertical harp

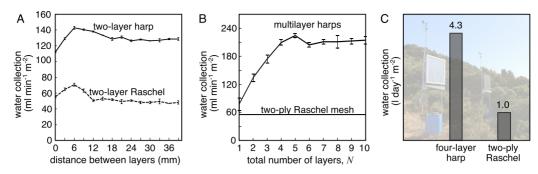

Figure 5. Yield measurements. (A) Effect of interlayer spacing on the yield of multilayer collectors. (B) Yield of multilayer harps $(1 \le N \le 10, s = 0.17, interlayer spacing of 6 mm)$ compared to two plies of Raschel mesh with s = 0.7 at a fog velocity $u_{\infty} = 4 \text{ m s}^{-1}$. arrangement. These frames were then stacked with different interlayer spacings to form multilayer fog collectors. The experiments reported here were done with a staggered relative alignment between successive layers. Note, however, that the staggered or in-line arrangements of layers had no significant effect on the performance of the collector.

Yield Measurements. To measure the yield, the prototypes were hung at a distance of 100 mm from the opening of a wind tunnel equipped with a fog chamber (see below). The water intercepted by the mesh was collected in a funnel leading to a graduated cylinder. Collection occurred over a total time interval of 15 min following an initial saturation period of 5 min.

Measurement of the Aerodynamic Collection Efficiency. Flow experiments were performed with an open-jet wind tunnel developed specifically to measure the efficiency of fog collector prototypes under natural conditions. The tunnel consists of two elements: a lower nebulization chamber for fog production and an upper flow chamber to accelerate the fog cloud and guide it into a uniform jet (Figure 4A). The nebulization chamber contained ~50 L of water within which was immersed a 300 W 12-head ultrasonic nebulizer (Model DK12-36). The fog produced in this chamber was injected into the upper chamber by a 16 W, 200 mm \times 200 mm ventilation fan. Within the flow chamber, an array of 16, 80 mm × 80 mm, computer fans accelerated the fog toward a contraction that converged the fog stream to a jet of 140 mm × 140 mm in cross section. Both the ventilation fan and the array of computer fans were powered through variable voltage transformers allowing us to set the jet velocity in the range 0.1-4.2 m s⁻¹. A honeycomb filter was placed at the upstream end of the contraction to eliminate turbulence and provide a homogeneous fog flow.

The flow of fog through and around the collector prototypes was visualized by using a Phantom V611 high-speed camera equipped with a Canon EF 100–400 mm telephoto zoom. Images were acquired at a rate of 4000 fps (exp 240 μ s) with a camera resolution of 1024 × 768 pixels and an image scale of 270 μ m/pixel. Analysis of the flow pattern was performed using a Matlab program first developed by Dr. A. F. Forughi at the University of British Columbia (Vancouver, Canada) and made freely available on Github (https://github.com/forughi/PIV).
