(Dated: August 5, 2012)

From unicellular ciliates to the respiratory epithelium, carpets of cilia display metachronal waves, long-wavelength phase modulations of the beating cycles, which theory suggests arise from hydrodynamic coupling. Experiments have been limited by a lack of organisms suitable for systematic study of flagella and the flows they create. Using time-resolved particle image velocimetry, we report the discovery of robust metachronal waves on the surface of the colonial alga Volvox carteri, whose large size and ease of visualization make it an ideal model organism. An elastohydrodynamic model of weakly-coupled oscillators, recast as interacting phase oscillators, offers an intuitive understanding of the emergence of metachronal waves, and confirms the role of compliance of oscillator orbits in producing fast, robust synchronization in a manner essentially independent of boundary conditions.

A major evolutionary breakthrough for unicellular organisms was the incorporation of appendages for self-propulsion. In ancestral eukaryotes, these took the form of 10 – 20 µm long hair-like motile organelles known as flagella which, together with their shorter ciliary version, are now common to most extant eukaryotic species. Whether in ciliates like Paramecium or the lining of the respiratory tract, cilia and flagella usually appear in large groups within which their individual motions tend to synchronize in patterns known as metachronal waves (MWs), modulations of the beating phase on the scale of many undulipodia [1]. Many theoretical studies [2–4] hint at a higher efficiency of propulsion by MWs, and suggest a possible selective advantage in strategies to stabilize their occurrence. Yet, the mechanisms behind their emergence and the selection of wave patterns are still unclear.

Early reports of correlated changes in the directions of flagellar beating and MW propagation [5] led to the hypothesis of a mechanical origin for synchronization, and motivated theoretical studies involving hydrodynamically coupled filaments driven by various types of internal engines [6–9]. While these models show a general tendency towards metachronal coordination, and help explain the generation and regulation of flagellar motion [10], their complexity prevents a simple understanding of the mechanism responsible for synchronization.

Minimal models of hydrodynamically coupled self-sustained oscillators with few degrees of freedom give insight into the emergence of MWs, and such synchronization has been investigated experimentally with rotating paddles [11], microrotors [12] and colloids in optical tweezers [13, 14], in simulations of rotating helices [15], and in several theoretical models of spheres driven along fixed trajectories [16–20]. We now know that under certain circumstances [17, 21] hydrodynamics alone can phase-lock two simple oscillators. This mechanism is probably not sufficient to account for the rapid and robust synchronization seen in biological systems [22], although flexibility in the oscillators’ trajectories [19] may remedy this problem. The precise mechanism leading to this is poorly understood, but there is increasing evidence for the interplay between orbit flexibility and hydrodynamic coupling as the origin of synchronization of flagellar pairs [23]. But synchronization of an isolated flagellar pair is not sufficient to guarantee metachronism of an ensemble, highlighting the need to understand better the link between local and global coordination. Progress hinges on the identification of suitable experimental systems to study MWs and test the intuition developed from theory, a goal which has remained unfulfilled.

Here we introduce the colonial green alga Volvox carteri [24] as a platform to study coordination in ensembles of eukaryotic flagella. Volvox is composed of thousands of biflagellate somatic cells embedded in a spherical extracellular matrix of radius $R \sim 200$ µm, beating towards the colony posterior in a nearly planar waveform. We report the first observation of MWs in such a simple, readily observable and easily manipulable system, and describe a straightforward method to quantify them. The flagella of Volvox are spaced relatively far apart compared to the celebrated ciliate Paramecium, and hence they are more nearly in the weak-coupling limit amenable to theory. Motivated by this, a minimal elastohydrodynamic model provides a semi-quantitative description of these MWs and confirms the importance of elasticity for robust synchronization. The model proposes a simple mechanism for the spontaneous choice of MW direction, and provides a unifying view of the synchronization patterns observed by previous studies in finite chains of oscillators.

Growth conditions for Volvox carteri f. nagariensis (strain EVE) have been described previously [25]. Individual colonies were inserted in a 25 × 25 × 5 mm observation chamber filled with fresh medium [26] seeded at 2 × 10^{-4} volume fraction with 0.5 µm polystyrene mi-
crospheres (Invitrogen, USA). Colonies were captured, oriented and held using two micropipettes with 100 μm diameter tips, hosted on pipette holders (World Precision Instruments, USA) held by motorized micromanipulators (Patchstar, Scientifica, UK), and connected to two manual microinjectors (Sutter Instruments Co., USA). Custom-made rotation stages mounted on each holder allowed rotation around the pipette’s axis [23]. We aligned the axis of each colony with the focal plane of a 40× Plan Fluor objective (NA 0.6) on a Nikon TE2000-U inverted microscope, and recorded 30 s long movies of the surrounding flow with a high-speed video camera (Fastcam SA3, Photron, USA) at 500 fps under bright field illumination. A long pass interference filter with a 10 nm transition ramp centred at 620 nm (Knight Optical, UK) prevented phototactic responses. The projection of the velocity field \( \mathbf{u} \) onto the focal plane was reconstructed using an open source Particle Image Velocimetry (PIV) [27] toolbox for Matlab (MatPIV), and decomposed into polar coordinates \( \mathbf{u} = u_r \mathbf{e}_r + u_\theta \mathbf{e}_\theta \) as in Fig. 1c.

For each *Volvox*, the radial component \( u_r(r^*, \theta, t) \) at \( r^* = 1.3R \) [Fig. 1(c)] is used to resolve spatially the beating phase of the somatic cells along the colony’s meridian opposite to the holding pipette. As shown in Fig. 1(a) kymographs of \( u_r(r^*, \theta, t) \) reflect clearly the propagation of a MW from the anterior towards the posterior of the colony. This is a *symplectic* MW, propagating in the same direction as the flagellar power stroke. Inspection of several colonies at different orientations confirms that the wave is mostly symplectic with only a minimal diaplectic (lateral) component. The wave parameters can be determined from the normalized correlation function

\[
C(\Delta \theta, \Delta t) = \frac{\langle \bar{u}_r(r^*, \theta, t + \Delta \theta) \bar{u}_r(r^*, \theta, t) \rangle}{\langle \bar{u}_r(r^*, \theta, t)^2 \rangle},
\]

where \( \bar{u}(r, \theta, t) \) is the deviation of the measured flow from its time average, and \( \langle \rangle \) denote averaging over \( t \) and \( \theta \). Fitting the autocorrelation function as \( C(\Delta \theta, \Delta t) = e^{-\Delta t/\tau} e^{-\Delta \theta/\lambda} \cos(k \Delta \theta - \omega \Delta t) \) yields the average beat frequency \( f = \omega / 2\pi \), autocorrelation decay time \( \tau \) and wavenumber \( k \) for each colony. Averaging over 60 colonies we obtain \( f = 33.0 \pm 3.2 \text{ Hz}, \tau = 0.10 \pm 0.06 \text{ s}, \) and \( k = 4.2 \pm 1 \), with individual data summarized in Figs. 1d-f. We emphasize that \( k > 0 \) for all colonies, indicating that despite the absence of any direct connections between somatic cells symplectic MWs are ubiquitous.

We now turn to a model for MWs. Inspired by the orbits of the flagellar tips of *Volvox* somatic cells [Fig. 2(a)], we generalise previous studies [17–19] and model the synchronous flagellar pair of an individual cell as a sphere of radius \( a \) elastically bound to a circular orbit of radius \( r_0 \), perpendicular to a no-slip plane, with the center at \( x^0 = (x^0, y^0, d) \) [Fig. 2(b)]. The sphere is driven by a constant tangential force \( f^{\text{dr}} \mathbf{e}_\phi \), and its speed \( \mathbf{v} \) follows the force-balance requirement of Stokes flow:

\[
\gamma(x) \cdot \mathbf{v} = -\lambda(r-r_0) \mathbf{e}_r - \eta \zeta \mathbf{e}_\zeta + f^{\text{dr}} \mathbf{e}_\phi.
\]

Here the spring stiffnesses \( \lambda \) and \( \eta \) in the radial (\( e_r \)) and transverse (\( e_\zeta \)) directions determine the deformation of the trajectory in response to external stresses. The friction tensor \( \gamma(x) = \)
The presence of a no-slip wall \[30\], which decays like \( \sim \frac{1}{r^5} \) here). For each set of parameters studied we simulate an isolated sphere, and recover the limit cyclic behavior of chains of 2 – 50 oscillators, with \( r_0/d = 0.5, 2 \leq t/d \leq 10 \), and spring stiffnesses 0.01 < \( \lambda \) < 10. While this parameter range the system evolves to a steady state profile in a few tens or hundreds of beating cycles, regardless of initial conditions. This phase-locking timescale increases with increasing stiffness of the orbit, and eventually diverges for \( \lambda \rightarrow \infty \) (holonomic constraint), in line with previous studies of geometrically constrained oscillators \[17, 21\]. The phase profiles after \( t/T = 1200 \) beats for 30 interacting spheres, representative of the general behavior, are summarized in Fig. 3.

For stiff springs the phase propagates outwards from the center of the chain, creating a chevron pattern previously encountered in similar systems \[19, 31\]. But as \( \lambda \) decreases the phase-locked pattern morphs into a symplectic metachronal wave \( \Phi \) that mimics natural boundary conditions for ciliary arrays. For \textit{Volvox}, \( \lambda d/f^{dr} \sim 0.1 \), which is in the symplectic regime of Fig. 3.

The dynamics of the chain of oscillators can be understood by studying the case \( N = 2 \). The interaction between two spheres induces only small perturbations around their limit cycles, and the coupled system can be described by the evolution of the phase difference \( \Delta = \Phi_2 - \Phi_1 \) and \( \Sigma = \Phi_2 + \Phi_1 = \omega^+ + S(\Delta, \Sigma) \), where \( D \) and \( S \) are effective coupling terms, and \( \omega^\pm = \omega_{\pm} \pm \omega_1 \). For sufficiently stiff springs, the phase difference evolves much more slowly than the sum, and we can average over a cycle of \( \Sigma \) to obtain \( \Delta = \omega^- + D(\Delta) \) and \( \Sigma = \omega^+ + S(\Delta) \). The functions \( D \) and \( S \) [Fig. 4(a)] are calculated numerically by simulating the system for many initial conditions [Fig. 4(b)]. Over the parameter range studied we consistently find a stable equilibrium point at a negative phase-lag \( \Delta_S < 0 \), and concurrently an increase in the average beating frequency \( \langle S(\Delta_S) \rangle > 0 \), a consequence of the lower drag at synchrony \[15, 19\].

Nontrivial phase locking results from
the interaction between the wall-modified flows, the compliance of the orbits, and the influence of deformations on phase speed. The flow components perpendicular to the wall modify the in-phase configuration that would be stable in an unbounded fluid [19] by compressing slightly the orbit of the upstream sphere, which speeds up, and dilating the orbit of the downstream one, which slows down. Stable equilibrium is then skewed to a negative phase lag. The observed phase locking is robust against dilating the orbit of the downstream one, which slows speed, reproduces the coordination of Volvox somatic cells in an open ended chain, which resembles a finite size array of flagella. This simple model may thus prove useful in clarifying the diverse types of MWs observed in nature, and in understanding more generally the nature of eukaryotic flagellar synchronization.

FIG. 4. (color online). Phase oscillator reduction. (a) Coupling functions \( D(\Delta) \) and \( S(\Delta) \) for a pair of interacting spheres. We have used the parameters \( r_0/d = 0.5, l/d = 2, a/d = 0.01, \lambda d/f^k = 1 \), for various initial conditions. (b) Phase difference, \( \Delta = \Phi_2 - \Phi_1 \), for large scale flagellar coordination is independent of \( \lambda \) negative values, and this precludes the emergence of a synchronization. (c) Amplitude of coupling functions for different spring stiffnesses.

This first report of MWs in the green alga Volvox carteri shows that large scale flagellar coordination is possible even in weakly coupled systems, and that detailed quantitative information on the average wave properties can be obtained with modern fluid dynamical techniques. The manner in which these properties depend on geometric factors such as the intercellular spacing and flagellar length will be addressed elsewhere. The model discussed here, with an interplay between wall-induced flows, orbit compliance, and deformation-induced changes in phase speed, reproduces the coordination of Volvox somatic cells in an open ended chain, which resembles a finite size array of flagella. This simple model may thus prove useful in clarifying the diverse types of MWs observed in nature, and in understanding more generally the nature of eukaryotic flagellar synchronization.
