## 1 Introduction

A general problem in physics is to deduce the macroscopic properties of a quantum system from a microscopic description. Such systems can only be described mathematically on a scale much smaller than the scales which are probed experimentally or on which the system naturally interacts with its environment. An obvious reason is that systems consist of particles whose individual behaviour is known and also whose interactions with neighbouring particles is known. On the other hand experimental probes interact only with systems containing large numbers of particles and the apparatus only responds to their large scale average behaviour. Statistical mechanics was developed expressly to deal with this problem but, of course, only provides a framework in which detailed methods of calculation and analysis can be evolved.
These notes are concerned with the physics of phase transitions: the phenomenon that in particular environments, quantified by particular values of external parameters such as temperature, magnetic field etc., many systems exhibit singulatities in the thermodynamic variables which best describe the macroscopic state of the system. For example:
(i) the boiling of a liquid. There is a discontinuity in the entropy,

$$
\Delta S=\frac{\Delta Q}{T_{c}}
$$

where $\Delta Q$ is the latent heat. This is a first order transition;
(ii) the transition from paramagnetic to ferromagnetic behaviour of iron at the Curie temperature. Near the transition the system exhibits large-range cooperative behaviour on a scale much larger than the inter-atomic distance. This is an example of a second order, or continuous, transition. Scattering of radiation by systems at or near such a transition is anomalously large and is called critical opalescence. This is because the fluctuations in the atomic positions are correlated on a scale large compared with the spacing between neighbouring atoms, and so the radiation scattered by each atom is in phase and interferes constructively.

Most of the course will be concerned with the analysis of continuous transitions but from time to time the nature of first order transitions will be elucidated. Continuous transitions come under the heading of critical phenomena. Broadly, the discussion will centre on the following area or observations:
(i) the mathematical relationship between the sets of variables which describe the physics of the system on different scales. Each set of variables encodes the properties of the system most naturally on the associated scale. If we know how to relate different sets then we can deduce the large scale properties from the microscopic description. Such mathematical relationships are called, loosely, renormalisation group equations, and, even more loosely, the relationship of the physics on one scale with that on another is described by the renormalisation group. In fact there is no such thing as the renormalisation group, but it is really a shorthand for the set of ideas which implement the ideas stated above and is best understood in the application of these ideas to particular systems. If the description of the system is in terms of a field theory then the renormalisation group approach includes the idea of the renormalisation of (quantum) field theories and the construction of effective field theories;
(ii) the concept of universality. This is the phenomenon that many systems whose microscopic descriptions differ widely nevertheless exibit the same critical behaviour. That is, that near a continuous phase transition the descriptions of their macrosopic properties coincide in essential details. This phenomenon is related to the existence of fixed points of the renormalisation group equations.
(iii) the phenomenon of scaling. The relationship between observables and parameters near a phase transition is best described by power-law behaviour. Dimensional analysis gives results of this kind but often the dimensions of the variables are anomalous. That is, they are different from the obvious or "engineering" dimensions. This phenomenon occurs particularly in low dimensions and certainly for $d<4$. For example in a ferromagnet at the Cutire temperature $T_{c}$ we find

$$
M \sim h^{\frac{1}{\delta}}
$$

where $M$ is the magnetisation and $h$ is the external magnetic field. Then the susceptibility, $\chi=\frac{\partial M}{\partial h}$, behaves like

$$
\chi \sim h^{\frac{1}{\delta}-1} .
$$

Since $\delta>1$, $\chi$ diverges as $h \rightarrow 0$. The naive prediction for $\delta$ is $3 . \delta$ is an example of a critical exponent which must be calculable in a successful theory. The coefficient of proportionality is the above relations is not universal and is not easily calculated. However, in two dimensions the conformal symmetry of the theory at the transition point does allow many of these parameters to be calculated as well. We shall not pursue this topic in this course.

Note. The general ideas of relating physical phenomena on widely differing scales by renormalisation group methods is widely applicable in many fields. For example:
(i) general diffusion models such as diffusion on fractal structures and the large scale effects of diffusive transport processes in fluid flow;
(ii) turbulence in fluids. The fluid velocity field, $\mathbf{u}(\mathbf{x}, t)$, of fully developed turbulence has energy density, as a function of wavenumber $\mathbf{k}$,

$$
k^{2} E(\mathbf{k}) \sim \frac{1}{V} \int d \mathbf{x} d \mathbf{y} \mathbf{u}(\mathbf{x}, t) \cdot \mathbf{u}(\mathbf{y}, t) e^{i \mathbf{k} \cdot(\mathbf{x}-\mathbf{y})}
$$

with $e(\mathbf{k}) \sim k^{-\frac{5}{3}}$ for large $k$.
This result is derived by "naive" dimensional analysis (Kolmogorov). However, a full solution of the Navier-Stokes equation can correct the exponent:

$$
E(\mathbf{k}) \sim k^{-\frac{5}{3}-\eta}
$$

where $\eta$ is the anomalous term.

## 2 The Phenomenology of Phase Transitions

Statistical systems in equilibrium are described by macroscopic, thermodynamic, observables which are functions of relevant external parameters, e.g., temperature, T, pressure, P, magnetic field, h. These parameters are external fields (they may be $\mathbf{x}, t$ dependent) which influence the system and which are under the control of the experimenter.
the observables congugate to these fields are:

| entropy | S | congugate to temperature | T |
| :--- | :---: | :---: | :---: |
| volume | V | congugate to pressure | P |
| magnetisation | M | congugate to mag. field | h |

Of course V and P may be swopped round: either can be viewed as an external field.
More common thermodynamic observables are the specific heats at constant pressure and volume, respectively $C_{P}$ and $C_{V}$; the bulk compressibility, $K$; and the energy density, $\epsilon$.
Equilibrium for given fixed external fields is described by the minimum of the relevant thermodynamic potential:

$$
\begin{array}{lll}
\mathrm{E} & \text { for fixed } & \mathrm{S}, \mathrm{~T} \\
\mathrm{~F} & \text { for fixed } & \mathrm{T}, \mathrm{~V} \\
\Phi & \text { for fixed } & \mathrm{T}, \mathrm{P} \\
\mathrm{~W} & \text { for fixed } & \mathrm{S}, \mathrm{P}
\end{array}
$$

A phase transition occurs at those values of the external fields for which one or more observables are singular. This singularity may be a discontinuity or a divergence. The transition is classified by the nature of the typical singularity that occur. Different phases of a system are separated by phase transitions. Broadly speaking phase transitions fall into two classes:
(1) 1st order
(a) Singularities are discontinuities.
(b) Latent heat may be non-zero.
(c) Bodies in two or more different phases may be in equilibrium at the transition point. E.g.,
(i) the domain structure of a ferromagnet;
(ii) liquid-solid mixture in a binary alloy: the liquid is richer in one component than is the solid;
(d) the symmetries of the phases on either side of a transition are unrelated.
(2) 2 nd and higher order: continuous transitions
(a) Singulaities are divergences. An observable itself may be continuous or smooth at the transition point but a sufficiently high derivative with respect to an external field is divergent. C.f., in a ferromagnet at $T=T_{c}$

$$
M \sim h^{\frac{1}{\delta}}, \quad \chi=\left(\frac{\partial M}{\partial h}\right)_{T} \sim h^{\frac{1}{\delta}-1} .
$$

(b) There are no discontinuities in quantities which remain finite through the transition and hence the latent heat is zero.
(c) There can be no mixture of phases at the transition point.
(d) The symmetry of one phase, usually the low-T one, is a subgroup of the symmetry of the other.

An order parameter, $\Psi$, distinquishes different phases in each of which it takes distinctly different values. Loosely a useful parameter is a collective or long-range coordinate on which the singular variables at the phase transition depend.
In a ferromagnet the spontaneous magnetisation at zero field, $\mathbf{M}(T)$, is such an order parameter, i.e.,

$$
\mathbf{M}(T)=\lim _{h \rightarrow 0+} \mathbf{M}(\mathbf{h}, T)
$$

then $|\mathbf{M}(T)|=0$ for $T \geq T_{c}$, and $|\mathbf{M}(T)|>0$ for $T<T_{c}$.
Note: $\Im\left(T-T_{c}\right)^{\frac{1}{2}}$ will not do.
$\Psi$ is not necessarily a scalar, but in general it is a tensor and is a field of the effective field theory which describes the interactions of the system on macroscopic scales (i.e., scales much greater than the lattice spacing). The idea of such effective field theories is common to many areas of physics and is a natural product of renormalisation group strategies.

## Examples

## (1) The Ising model in $\mathbf{3}$ dimensions.

The theory is defined on the sites of a 3D cubic lattice and the variable on the site labelled by $\mathbf{n}$ is $\sigma_{\mathbf{n}} \in Z_{2}$. There is a nearest neighbour interaction and an interaction with an external magnetic field, $h$. Then the energy is written as

$$
H=J \sum_{\mathbf{n}, \mu} \sigma_{\mathbf{n}} \sigma_{\mathbf{n}+\mu}-h \sum_{\mathbf{n}} \sigma_{\mathbf{n}},
$$

where $\mu$ is the lattice vector from a site to its nearest neighbour in the positive direction, i.e.,

$$
\mu \in(1,0,0)(0,1,0)(0,0,1) .
$$

The order parameter is the magnetisation,

$$
M=\frac{1}{V} \sum_{\mathbf{n}} \sigma_{\mathbf{n}}
$$

where V is the number of sites in the lattice. Note, that whilst the $\sigma_{\mathrm{n}}$ are discrete, $M$ is a continuous variable, $-1 \leq M \leq 1$ in the limit $V \rightarrow \infty$.
(2) $\mathrm{H}_{2} \mathrm{O}$

Look at the two phases of liquid and vapour. The order parameter is the density, $\rho$, which is large for the liquid phase relative to its value for the vapour phase.

The properties of both systems, their similarities and differences are best exhibited by showing the various phase diagrams.

## PHASE DIAGRAMS

## Ising model

$\mathrm{h}=0 \pm$
$\mathrm{M}=\mathrm{M}^{ \pm}(\mathrm{T})$
$\mathrm{h}>0$ and $\mathrm{h}<0$
$\mu$ is the chemical potential, and $\mu=\mu_{c}(T)$ is the line of first order transitions in the $(\mu, T)$ plot for $\mathrm{H}_{2} 0$. It corresponds to the line $h=0$ in the $(h, T)$ plot for the Ising model.
(i) Approach along (a) gives a 1st order transition whilst approach along (b) through the critical point gives a 2 nd order transition.
(ii) The order parameters are:

## magnetisation $M$

$$
\text { density } \rho
$$

The congugate fields are:

## magnetic field $h$

chemical potential, $\mu$ or pressure, $P$
(iii) The behaviour near $T=T_{c}\left(t=\left(\left(T-T_{c}\right) / T_{c}\right)\right.$
(a) $t \rightarrow 0-, h=0 \pm$
$M(T) \sim|t|^{\beta}$

Clear symmetry in curve
(b) $t \rightarrow 0+, h=0$

Susceptibility

$$
\chi=\left(\frac{\partial M}{\partial h}\right)_{T}
$$

$$
t \rightarrow 0-, \mu-\mu_{c}(T)=0 \pm
$$

$$
\rho(T)-\rho_{c} \sim|t|^{\beta_{+}}
$$

$$
\rho(T)-\rho_{c} \sim|t|^{\beta_{-}}
$$

No obvious symmetry but experimentally $\beta_{+}=\beta_{-}$
(c) $t=0, h \rightarrow 0+$

$$
M \sim h^{\frac{1}{\delta}}
$$

$t=0, \mu-\mu_{c} \rightarrow 0+$
$\rho-\rho_{c} \sim\left(\mu-\mu_{c}\right)^{\frac{1}{\delta}}$
$\beta, \gamma, \delta$ are examples of critical exponents.
(iv) Coexisting phases

(a) States between the curves I and II are physical but metastable. They do not violate thermodynamic inequalities. In the PV plot this is equivalent to

$$
\left(\frac{\partial P}{\partial V}\right)_{T}<0
$$

which means that the compressibility is positive. This inequality is derived from entropy being a maximum in equilibrium. Howver, these states are unstable against changing to the mixed system, e.g., domains in the Ising model (or ferromagnet), and liquid-gas mixture for water. The continuous curves shown are the $(h, M)$ and $(P, V)$ curves for a pure phase. E.g., the Van-der-Waals equation of state:

$$
\left(P+\frac{a}{V}\right)(V-b)=c T
$$

(b) The Maxwell construction gives the true equilibrium curve taking into account the formation of the mixed system. The mixture is of the two phases A and B. The rule for finding the interpolation is illustrated in the case of $\mathrm{H}_{2} \mathrm{O}$ :

$$
P_{A}=P_{B}, \quad \mu_{A}=\mu_{B} \Rightarrow \mu_{A}-\mu_{B}=\int_{A}^{B} v d P=0
$$

where $v=V / N$, and $N$ is the number of particles. This is the equal areas rule of Maxwell.
What happens is that boundaries between phases or domains form. In each domain the magnetisation is oriented differently and so the bulk average magnetisation can be any value in the range $-|M|$ to $|M|$, where $|M|$ is the magnetization of a pure domain. The walls do increase the energy of the system by $\Delta \epsilon$ and there is also an increase in the entropy, $\Delta S$. since there are many ways of realising the mixed state. However, the resultant change in the free-energy, $\Delta F=\Delta \epsilon-$ $T \Delta S$, depends on the surface area of the walls and is negligible in the limit of very large volume. Of course, the actual way in which domains, or bubbles, form and move is very important (e.g. in the early universe, cosmic string formation etc.) but needs more analysis than the embodied in the Maxwell construction.

### 2.1 The general structure of phase diagrams

A thermodynamic space, $Y$, is some region in an s-dimensional real vector space spanned by field variables $y_{1}, \ldots, y_{s}$ (e.g., $P, Y, T, \mu, \ldots$ ). In $Y$ there will be points of two, three, etc. phase coexistence (c.f. A and B in $\mathrm{H}_{2} \mathrm{O}$ plot above), together with critical points, multicritical points, critical end points, etc.. $Q$ is the totality of such points. The phase diagram is the pair $(Y, Q)$.
Points of a given type lie in a smooth manifold, $M$, say. The codimension, $\kappa$, of these points is defined by

$$
\kappa=\operatorname{dim}(Y)-\operatorname{dim}(M)
$$

E.g., two phase ponts have $\kappa=1$; critical points (points that terminate two phase lines) have $\kappa=2$.
There do not exist any known rules for constructing geometrically all acceptable phase diagrams, $(Y, Q)$ : we cannot construct all the phase diagrams which could occur naturally.

### 2.1.1 Structures in a phase diagram: a description of $Q$

I assume that there are $C$ components in the system, and hence there are $(c+1)$ external fields: $\mu_{1}, \ldots, \mu_{c}, T$. Then $\operatorname{dim}(Y)=(c+1)$.
(a) Manifolds of multiphase coexistence.

The Gibbs phase rule states that the coesistence of $m$ phases in a system with $C$ components has

$$
f=c+2-m
$$

where $F$ id the dimension of the manifold of $m$-phase coexistence.
proof: $\operatorname{dim}(Y)=(c+1)$ and hence the manifold has codimension $\kappa=$ $(c+1-f)$. But $\kappa=(m-1)$ since $k$ external fields must be tuned to bring about m-phase coexistence.
(b) An ordinary critical point has $\kappa=2$ and occurs when two coexisting phases become identical:

two coexisting phases

phases are identical: $\mathrm{a}=\mathrm{b}$

(c) A critical end-point occurs with codimension $\kappa$ when two coexisting phases become identical in the presence of $(\kappa-2)$ other phases:

An example of all these structures in a three dimensional phase diagram is shown below.

thus the critical end-point terminates a line of critical points and also terminates a line of triple points.

Note that a phase diagram can often only be properly understood if plotted in the space of all relevant parameters. E.g., the Gibbs rule might seem to be violated since too many phases are coexisting at one point. However, if the space is enlarged in dimension this will be seen as a special case which only occurs for a particular cross-section of the enlarged space;

(d) A tricritical point has $\kappa=4$. Its nature is most easily seen first in three dimensions. This is already a special case since we can only be sure it will appear in four dimensions. We suppose we have taken the appropriate cross-section of the 4D space. this often occurs naturally since some of the parameters are naturally set to the special values necessary to show up the tricritical point: e.g., by symmetry considerations.

2D

The hatched surfaces are 1st-order surfaces: surfaces of two phase coexistence. Thus the 1st order line in 2D is really a line of triple points (three phase coexistence) in higher dimensions.
A less special 2D cross-section of the same model will be:

Here we have set $h=0$ (see 3D plot) but have changed the value of a fourth parameter $u$.
(e) A bicritical point is a critical point at which two critical lines terminate. A typical phase diagram is: A model which has a phase diagram like this

is given by the Hamiltonian

$$
H=-J \sum_{<i j>} \mathbf{s}_{i} \cdot \mathbf{s}_{j}+\frac{1}{2} g \sum_{i}\left(\left(\mathbf{s}_{i}^{z}\right)^{2}-\frac{1}{2}\left(\left(\mathbf{s}_{i}^{x}\right)^{2}+\left(\mathbf{s}_{i}^{y}\right)^{2}\right)\right)
$$

$<i j>$ means nearest neighbour pairs, i.e., it labels the links on the lattice.
$\mathbf{s}_{i}$ is a vector at the i-th site with $\left|\mathbf{s}_{i}\right|=1$.

For low T thermal fluctuations can be ignored and it is safe to just find the configuration (i.e., set of values) of spins $\left\{\mathrm{s}_{i}\right\}$ which minimises $H$. Since $J>0$ the first term causes the spins to align with each other to give ferromagnetic ordering.

$$
g<0 \quad \text { Ordering is prefered along z-axis. This is phase B. }
$$

## 3 LANDAU-GINSBERG THEORY AND MEAN FIELD THEORY14

$g>0 \quad$ Ordering is prefered in the $x y$-plane $\perp$ z-axis. This is phase A.<br>$g=0 \quad$ Neither A nor B prefered: two-phase coexistence.

#### Abstract

For high T ordering is absent: it is destroyed by thermal fluctuations. For $g \neq 0$ as T increases we must have a second order transition from ferromagnetic to paramagnetic phases. The surfaces to the low-T side of the lines of critical points are first-order surfaces. This can be seen by imposing a magnetic field $\mathbf{h}$ on the system with components both $\|$ and $\perp$ to the z -axis and adding the magnitude, $h$, of $\mathbf{h}$ (including sign) as a third orthogonal axis to generate a 3D phase plot of which our 2D plot is the $h=0$ cross-section. Then as $h$ changes sign the magnetisation, $\mathbf{M}$, changes discontinuously at $h=0$. This occurs as the surfaces in our 2D phase diagram on the low-T side of the critical lines are punctured, and hence they are in fact first-order surfaces. Of course, because the order parameter is a vector the possible patterns of behaviour and the competition between the effects of the terms governed by the coupling, $g$, and by $h$ is, in general, complicated. An r-critical point is where r critical lines terminate.

(f) A critical point of $n$-th order has $\kappa=n+2$ and is complicated.

## 3 Landau-Ginsberg theory and mean field theory

The Landau-Ginsberg theory is a phenomenological theory describing all types of phase transition which can be derived from the more complete theory. It is a classical approach which breaks down in its simple form for low dimensions. However, it can be used for developing the structure of phase transitions and phase diagrams. Landau theory gives the correct prediction for critical indices in dimensions $d>d_{c}$, where $d_{c}$ is a critical dimension which is different for different kinds of critical point. E.g., for an ordinary critical point $d_{c}=4$, and for a tricritical point $d_{c}=3$.
Mean field theory is a method of analysing systems in which the site variable (spin etc.) is assumed to interact with the mean field of the neighbours with which it interacts. In a spin model each of the neighbouring spins has the value of the mean magnetisation per spin, $\mathbf{m}$. The problem now reduces to that of a single spin in an external field and can easily be solved. By demanding that the mean value of the spin in question is $\mathbf{m}$ the solution yields a non-linear equation expressing this assumption of self-consistency and from which $\mathbf{m}$ can be calculated as a function of T . The approximation of the method is that it ignores fluctuations in the spins about their mean. It will turn out that Landau theory suffers from the same deficiency as we shall demonstrate. Mean field theory and Landau theory give the same, classical, predictions for critical exponents. We shall consider the following example.

## 3 LANDAU-GINSBERG THEORY AND MEAN FIELD THEORY15

Let the order parameter be $M$, and expand the free energy, A, as

$$
A=A_{0}+\frac{1}{2} A_{2} M^{2}+\frac{1}{4} A_{4} M^{4}+\frac{1}{6} A_{6} M^{6}+\ldots
$$

with $A_{2} \propto\left(T-T_{c}\right)$.
There are no terms with odd powers of $M$. These can be present in principle but can be consistently excluded by symmetry considerations if the microscopic Hamiltonian is invariant under $M \rightarrow-M$. If odd powers of $M$ are present then generally the theory has only first order transitions, although higher order transitions cannot be totally excluded. $T_{c}$ is a complicated function of the couplings in the original, microscopic, Hamiltonian as are the other coefficients, $A_{2 n}$. It is an assumption that $A_{2}$ is analytic in $T$ : an assumption that can only be plausibly justified under certain circumstances. This assumption as well as others is wrong if the dimension is low enough.

Equilibrium is given by minimising A:

$$
\frac{d A}{d M}=0
$$

The observable value of the order parameter, $M(T)$, is the solution of this equation. Then

$$
|M(T)|=\left|\frac{A_{2}}{A_{4}}\right|^{\frac{1}{2}}\left(1+\frac{1}{2} \frac{A_{6} A_{2}}{A_{4}^{2}}+\ldots\right) .
$$

Thus as $T \rightarrow T_{c}$

$$
|M(T)| \sim\left|T-T_{c}\right|^{\frac{1}{2}} \Rightarrow \beta=\frac{1}{2}
$$

We can rewrite the expression for $M(T)$ as

$$
M(T)=\left|\frac{A_{2}}{A_{4}}\right|^{\frac{1}{2}} m(x), \quad \text { where } \quad x=\frac{A_{6} A_{2}}{A_{4}^{2}} .
$$

If we assign to $M$ a dimension of $(-1)$ and dimension $d$ to $A$ then the coefficients $A_{2 n}$ have dimension $(d+2 n)$. Thus in this artifical dimensional analysis we find that $x$ is dimensionless and that the critical exponent is predicted on dimensional grounds. The analysis above is only possible if $A_{4}>0$, in which case $A_{6}$ only occurs in the correction terms. If $A_{4}<0$ then we require $A_{6}>0$ to stabilize the calculation and the results are different (see below). In the former case since only $A_{2}$ and $A_{4}$ are important the critical exponent follows uniquely from the dimensional argument.
$\mathrm{A}_{4}>0$
If a field $h$ is applied then the symmetry is broken and

$$
A=A_{0}-h M+\frac{1}{2} A_{2} M^{2}+\frac{1}{4} A_{4} M^{4} .
$$

## 3 LANDAU-GINSBERG THEORY AND MEAN FIELD THEORY16

At $T=T_{c}\left(A_{2}=0\right)$ the condition for equilibrium is

$$
-h+A_{4} M^{3}=0 \quad \Rightarrow \quad M \sim h^{\frac{1}{3}} \quad \Rightarrow \quad \delta=3 .
$$

For $T>T_{c}$ we have $\left(t=\frac{\left(T-T_{c}\right)}{T_{c}}\right)$

$$
-h+a_{2} T_{c} t M+A_{4} M^{3}=0
$$

Then the susceptibility is given by

$$
\chi=\left(\frac{\partial M}{\partial h}\right)_{h=0}=\frac{1}{a_{2} T_{c}} t^{-1} \Rightarrow \gamma=-1 .
$$

The curve of $\pm M(T)$ vs $T$ is a parabola: For $T<T_{c}$ we find

$$
h=-a_{2}\left|T-T_{c}\right| M+A_{4} M^{3},
$$

where in general $A_{4}$ is a function of $T$ which does not vanish at $T=T_{c}$. Thus the equation of state has the form

$$
h=-a(T) M+\beta(T) M^{3}+\ldots
$$

Then

$h>0$

$\mathrm{h}<0$

## 3 LANDAU-GINSBERG THEORY AND MEAN FIELD THEORY17

If $h$ is tuned from positive to negative the true minimum describing equilibrium changes from one to the other, but it takes time to re-establish th equilibrium especially if the intervening barrier is high. Consequently, the system can be in a metastable state corresponding to the local but not global minimum. This is the phenomenon of hysteresis. What happens is clear from the equation of state:

(i) For $h_{1}$ there is unique minimum and the state is stable.
(ii) For $h_{2}$ there are two minima (a) and (c) and a maximum (b). State (c) is stable and (a) is metastable, but (b) is unstable corresponding to a maximum of $A$ and thermodynamic inequalities are violated here.
(iii) Follow what happens as $h$ decreases from $h_{1}$ through $h_{2}$ and $h_{3}$ and eventually becomes large and negative: $M$ varies smoothly as a function of $h$ and metastability (supercooling) occurs, then at (d) the state becomes unstable and any fluctuation precipitates the change to the true equilibrium state.

Plots of $A$ vs $M$ for the different $h$ values make this interpretation clear:

The Maxwell construction tells us that the stable state is not most generally characterised by a constant $M$. Locally $M$ is a constant but it can change globally giving a domain structure. The Maxwell construction corresponds to the situation when $h=0$ and there are two degenerate minima associated with the two different domains that can co-exist. Thus at $h=0$ any value of $M$ between these minima is possible and corresponds to an appropriate mixture of domains. The above analysis relies on the smoothness and differentiability of all functions $A, h, M$ and can never directly address the mixed-phase system.

## 3 LANDAU-GINSBERG THEORY AND MEAN FIELD THEORY18

$\mathrm{A}_{\mathbf{4}} \leq \mathbf{0}$
As $T$ decreases $A(M)$ behaves qualitatively differently depending on whether $A_{4}>0$ or $A_{4} \leq 0:$

second-order transition at $T=T_{c}$

first-order phase transition at $\mathrm{T}_{0}, \mathrm{~T}_{0}>\mathrm{T}_{\mathrm{C}}$

Hence the system passes from a second-order transition to a first-order transition as $A_{4}$ changes sign and becomes negative.
The stationary points are at $M=0$ and at

$$
M^{2}=\left[-A_{4} \pm\left(A_{4}^{2}-4 A_{2} A_{6}\right)^{\frac{1}{2}}\right] / 2 A_{6} \equiv M_{ \pm}^{2}
$$

The + sign gives the minima and the - sign the maxima.
$T_{0}$ is determined by $A(M)=0$ having a double root at $M= \pm M_{+}$(note that $A_{0}$ is set to zero so that $A(0)=0$ is the minimum for $T>T_{0}$ ). The solution is

$$
A_{2}=\frac{3}{16} \frac{A_{4}^{2}}{A_{6}}
$$

and at the transition

$$
\left(\Delta M^{2}\right)^{2}=M_{+}^{2}=-\frac{3}{4} \frac{A_{4}}{A_{6}}
$$

Thus the point $T=T_{c}, A_{4}=0$ separates the first-order line from the second-order line: this is a tricritical point. To see the tricritical point these two parameters have to take these special values and this requires tuning two external fields in the phase diagram.
In the space of physical fields, denoted by $T$ and $g$ (e.g., $g$ can be identified with a chemical potential controlling the relative abundances in a two component system), the phase diagram has the form:

## 3 LANDAU-GINSBERG THEORY AND MEAN FIELD THEORY19

Alternaltively the phase diagram in $\left(A_{2}, A_{4}\right)$ space takes the form: vskip 5 truemm

(i) Both trajectories (a) and (b) exhibit a second-order transition.
(ii) Trajectory (a) passes through the TCP and lies entirely within the tricritical region. The transition is characterised entirely by the properties of the TCP, and all critical exponents are tricritical ones.
(iii) Trajectory (b) exhibits an ordinary second order transition. However, it starts in the tricritical region and so initially the divergence of the relevant quantities is controlled by the TCP. Eventually it passes into the critical region and the transition is characterised by the line of ordinary critical points and the critical exponents that are given above.

In other words we only see a transition controlled by the TCP when we apporoach along a trajectory lying in the tricritical region. For trajectories that pass from one region to another we see a change in the critical behaiviour. This change is characterised by crossover exponents.

## 3 LANDAU-GINSBERG THEORY AND MEAN FIELD THEORY20

At the TCP $A_{4}=0$, and so we have

$$
|M|=\left|\frac{A_{2}}{A_{6}}\right|^{\beta_{t}} \quad \text { with } \quad \beta_{t}=\frac{1}{4}
$$

New exponents can be defined:

$$
\begin{aligned}
\left(T_{0}-T_{c}\right) & \sim\left(-A_{4}\right)^{\frac{1}{\psi}} \quad \text { with } \quad \psi=\frac{1}{2} \\
\Delta M & \sim\left|A_{4}\right|^{\beta_{u}} \quad \text { with } \quad \beta_{u}=\frac{1}{2}
\end{aligned}
$$

where $\Delta M$ is the discontinuity in $M$ across the first-order line $\left(A_{4}<0\right)$. then for small $A_{4}$ we can write

$$
\begin{aligned}
|M| & =\left|\frac{A_{2}}{A_{6}}\right|^{\beta_{t}} m(x), \\
x & =\frac{A_{4}}{2\left|A_{2}\right|^{\frac{1}{2}} A_{6}^{\frac{1}{2}}}
\end{aligned}
$$

To see tricritical behaviour along a trajectory we clearly need $x$ small, i.e.,

$$
A_{4}^{2} \ll 4\left|A_{2}\right| A_{6}
$$

This defines a parabola in the $\left(A_{4}, A_{6}\right)$ plane separating the tricritical from critical regions. This is shown on the figure. In the space of physical parameters it translates into a similar shaped curve defining the two regions controlled by the TCP and ordinary critical points respectively.

The general theory of continuous phase transitions can be encoded in terms of scaling functions and relies on dimensional analysis together with some assumptions about the behaviour of the scaling functions for small argument. If naive or engineering dimensions are used this is generally a recoding of Landau theory but is often used to describe the behaviour of the relevant thermodynamic variables as a function of the actual external fields and hence parametrises the experimental observations.
Add a magnetic field, $h$, with contribution to the free energy of $-h M$. Then we can always write

$$
A=\frac{\left|A_{2}\right|^{\frac{3}{2}}}{A_{6}^{\frac{1}{2}}} F\left(\frac{A_{4}}{2\left|A_{2}\right|^{\frac{1}{2}} A_{6}^{\frac{1}{2}}}, \frac{h A_{6}^{\frac{1}{4}}}{\left|A_{2}\right|^{\frac{5}{4}}}\right) .
$$

The point is that the equilibrium free energy, $A$, can always be written in terms of dimensionless ratios in this way. As before assign dimension $(-1)$ to M and dimension $d$ to A , and then $A_{n}$ has dimension $(d+n)$. The above expression is then a general way of writing the dependence of $A$ at equilibrium on the coefficients $A_{2 n}$ in terms of a scaling function, $F$. Note that since $A_{6}$ is always taken as positive it causes no problem in the denominators.

## 3 LANDAU-GINSBERG THEORY AND MEAN FIELD THEORY21

We now compare with a standard form parametrising $A$ near the TCP:

$$
A=\left|T-T_{c}(\tilde{g})\right|^{2-\alpha} F\left(\frac{\tilde{g}}{\left|T-T_{c}(\tilde{g})\right|^{\phi}}, \frac{h}{\left|T-T_{c}(\tilde{g})\right|^{\Delta}}\right),
$$

where $\tilde{g} \propto A_{4}$, and thus measures the distance from the TCP along the tangent to the critical line at the TCP. Note that $\tilde{g}$ has been substituted for the field $g$ as the second independent external field: the critical line is thus parametrised as $T_{c}(\tilde{g})$. The TCP then is at position $\left(0, T_{t}\right)$ in the $(\tilde{g}, T)$ plane where $T_{t}=T_{c}(0)$. Labelling the critical exponents at the TCP by suffix, $t$, we clearly have

$$
\alpha_{t}=\frac{1}{2}, \quad \phi_{t}=\frac{1}{2}, \quad \Delta_{t}=\frac{5}{4} .
$$

The following examples clarify the interpretation.
(i) $h=0, \tilde{g}=0, T \rightarrow T_{t}$ such that $\frac{\tilde{g}}{\left|T-T_{t}\right|^{\phi_{t}}} \equiv x$ is fixed. Then

$$
A=\left|T-T_{t}\right|^{\frac{3}{2}} F(x, 0) \quad \text { with } \quad F(0,0) \quad \text { finite. }
$$

We see tricritical behaviour and since $\tilde{g} \sim\left|T-T_{t}\right|^{\phi_{t}}$ the trajectory lies in the tricritical region. $\phi_{t}$ is the cros-over exponent.
(ii) $h \rightarrow 0$, $\tilde{g}$ fixed, $T \rightarrow T_{c}$.

$$
A=\left|T-T_{c}\right|^{\frac{3}{2}} F\left(\frac{\tilde{g}}{\left|T-T_{c}\right|^{\frac{1}{2}}}, 0\right) .
$$

the argument of $F$ is not under control and so we rearrange the expression:

$$
A=\frac{\left|T-T_{c}\right|^{2}}{\tilde{g}} G\left(\frac{\left|T-T_{c}\right|^{\frac{1}{2}}}{\tilde{g}}, 0\right),
$$

where $G(z, 0)=z F\left(\frac{1}{z}, 0\right)$ and $G(0,0)$ is finite and non-zero. This property of $G$ is an assumption in the general theory and could be violated. It does follow from the standard Landau analysis and hence if it turned out to be false in an experiment it would signal a breakdown of the Landau theory. The goal then would be to rescue the dimensional analysis approach by assigning values to the dimensions of the parameters different from the naive ones but which render the scaling functions $F$ and $G$ well behaved for small argument.
In this case we find that $A$ shows the normal critical behaviour associated with an ordinary critical point, namely

$$
A \sim\left|T-T_{c}\right|^{2-\alpha} \quad \text { with } \quad \alpha=0
$$

(iii) $T=T_{t}, \tilde{g} \neq 0, h \neq 0$

$$
A=\lim _{T \rightarrow T_{t}}\left|T-T_{t}\right|^{2-\alpha_{t}} F\left(\frac{\tilde{g}}{\left|T-T_{t}\right|^{\phi_{t}}}, \frac{h}{\left|T-T_{t}\right|^{\Delta_{t}}}\right)
$$

## 3 LANDAU-GINSBERG THEORY AND MEAN FIELD THEORY22

but $A$ remains non-zero for $h \neq 0$ and we must be able to rewrite $A$ in the limit as

$$
A=h^{\frac{2-\alpha_{t}}{\Delta_{t}}} J\left(\frac{\tilde{g}}{h^{\frac{\phi_{t}}{\Delta_{t}}}}\right),
$$

i.e., $F$ must have a singularity that cancels the external factor of $\left|T-T_{t}\right|^{2-\alpha_{t}}$. Thus

$$
A=h^{\frac{6}{5}} J\left(\frac{\tilde{g}}{h^{\frac{2}{5}}}\right) .
$$

If we assume $J(0)$ is non-zero and finite then at the TCP

$$
A \sim h^{\frac{6}{5}} \text { and } M=-\frac{\partial A}{\partial h} \sim h^{\frac{1}{5}} \Rightarrow \delta_{t}=5 .
$$

This result can be derived much more directly from the Landau theory: at $T=T_{t}$ both $A_{2}$ and $A_{4}$ are zero and so we can write

$$
A=-h M+A_{6} M^{6} .
$$

Thus we find that

$$
\frac{\partial A}{\partial M}=0 \quad \Rightarrow \quad M \sim h^{\frac{1}{5}}
$$

However, it is important to see how the parametrisation in terms of scaling functions works, and, as has already been remarked, this form of parametrisation is more general than the naive Landau theory: the assumption that $F(0,0)$ etc. are non-zero and/or finite breaks down when Landau theory ceases to be valid.

A summary of the critical indices is

|  | $A \sim\|t\|^{2-\alpha}$ <br> $\alpha$ | $M \sim(-t)^{\beta}$ <br> $\beta$ | $\chi \sim\|t\|^{-\gamma}$ <br> $\gamma$ | $M \sim h^{\frac{1}{\delta}}$ <br> $\delta$ | cross-over <br> $\phi_{t}$ |
| :---: | :---: | :---: | :---: | :---: | :---: |
| CP | 0 | $\frac{1}{2}$ | -1 | 3 | $\frac{1}{2}$ |
| TCP | $\frac{1}{2}$ | $\frac{1}{4}$ | -1 | 5 | $\frac{1}{2}$ |

$$
\begin{array}{rlrl}
\left(T_{0}-T_{c}\right) & \sim\left|A_{4}\right|^{\frac{1}{\psi}} & \psi & =\frac{1}{2} \\
\Delta M & \sim\left|A_{4}\right|^{\beta_{u}} & \beta_{u}=\frac{1}{2} .
\end{array}
$$

To finish this section we look in general at the Landau model with one parameter.

## 3 LANDAU-GINSBERG THEORY AND MEAN FIELD THEORY23

Let the thermodynamic potential be $\Psi$ and the order parameter $x$. Then

$$
\Psi=a_{0}+a_{1} x+a_{2} x^{2}+\ldots x^{2 q}
$$

We assume that the coefficient of the highest order term is 1 . This means that higher order terms will not affect the phase structure since the coefficient of this term will not be allowed to vanish at any point in that part of the phase space in which we are interested. In addition this highest power is even. This ensures stability, i.e., $\Psi$ has a global minimum characterising equilibrium.
The $a_{i}$ are thermodynamic field variables which span the phase space, $Y$, and for a given choice of the $a_{i}$ the stable thermodynamic state is identified with the value of $x$ which minimises $\Psi$. Choose $a_{0}$ such that this minimum is always at $\Psi=0$ : this simply fixes the origin of $\Psi$. Then we can write

$$
\Psi=\prod_{j=1}^{q}\left[\left(x-b_{j}\right)^{2}+d_{j}\right]
$$

where $\forall j$ the $b_{j}$ are real and the $d_{j}$ are real and non-negative. However, at least one of the $d_{j}$ is zero since $a_{0}$ has been chosen appropriately. Then $\Psi$ can be represented by the configuration of a set of points $\left(b_{j}, d_{j}\right)$ in the upper half of the $(b, d)$ plane. Consider the following examples.

## (i) m-phase coexistence

The minimum of $\Psi$ occurs for $m$ distinct values of $x$. These are identified with the $m$ coexisting phases and it corresponds to $m$ of the $d_{j}$ being zero. In general this requires $(m-1)$ constraints on the $d_{j}$ and hence the manifold of $m$-phase coexistence has codimension $\kappa=m-1$. For $m=2$ the configuration takes the form:

(ii) A critical point

A critical point occurs if two of the $d_{j}$ are zero and the corresponding $b_{j}$ coincide:

## 3 LANDAU-GINSBERG THEORY AND MEAN FIELD THEORY24

- = two coinciding points

For this configuration

$$
\Psi=(x-b)^{4}+\alpha_{5}(x-b)^{5}+\ldots
$$

There is no quadratic term $(x-b)^{2}$ and hence have a second order transition. This is a more general situation than before where we imposed symmetry under $x \rightarrow-x$ for simplicity.

The additional constraint on the $b_{j}$ means that $\kappa$ is one more than for two phase coexistence, i.e., $\kappa=2$.

## Remarks

(a) All points of $m$-phase coexistence can be continuously transformed into each other: inspect diagrams of the kind shown in (i) above. Hence they all lie on one manifold.
(b) There is only one manifold of critical points. This is clear from (ii) above.

## (iii) Critical end-points

or alternatively

## 3 LANDAU-GINSBERG THEORY AND MEAN FIELD THEORY25

It is not possible to pass continuously between these two diagrams and hence there are two distinct manifolds of critical end-points separated by a
(iv) Tricritical point

This point has $\kappa=4$ : two constraints occur because there are three coexisting phases (i.e., $m=3 \Rightarrow(m-1)$ constraints), and two further constraints arise because of the requirement that the relevant $b_{j}$ coincide. Howver, $\kappa$ is just the number of such constraints.
(v) Multicritical points of order $r$
$r$ of the $d_{j}$ are zero and the corresponding $b_{j}$ coincide. thus

$$
\kappa=(r-1)+(r-1)=2 r-2 .
$$

clearly we can determine how the manifolds fit together by following the flow of points in $(b, d)$ space as the $a_{i}$ vary.

## 4 The Partition Function and Field Theory

The partition function $\mathcal{Z}$ is defined by

$$
\mathcal{Z}=\int\{d \phi\} e^{-\beta H(\phi)}
$$

where $\phi(\mathbf{x})$ is a generic field degree of freedom and $\beta=1 / k T . H(\phi)$ is the Hamiltonian given by

$$
H(\phi)=\int_{\Lambda^{-1}} d \mathbf{x} \mathcal{H}(\phi(\mathbf{x}))
$$

where $\mathcal{H}(\phi(\mathbf{x}))$ is the Hamiltonian density. $\Lambda$ is the large momentum cut-off which, for a lattice of spacing $a$, is $\Lambda=2 \pi / a$. In this case the integral will be a sum over all sites of a discrete Hamiltonian density. The crucial point is that there will, in general, be a cut-off of some kind.
We shall assume that the coefficients in $H$ depend only on the volume, $V$, of the system. Then, for a given temperature $T$ and volume $V$ of a subsystem the equilibrium probability density for finding the subsystem with field configuration $\phi(\mathbf{x})$ is

$$
p(\phi)=\frac{1}{\mathcal{Z}} e^{-\beta H(\phi)} .
$$

Then the entropy $S$ is given by

$$
\begin{aligned}
S & =-k \int\{d \phi\} p(\phi) \log (p(\phi)) \\
& =-k \int\{d \phi\} \frac{1}{\mathcal{Z}} e^{-\beta H(\phi)}(-\beta H-\log \mathcal{Z}) \\
& =k(\beta U+\log \mathcal{Z})
\end{aligned}
$$

where

$$
U=\frac{1}{\mathcal{Z}} \int\{d \phi\} H(\phi) e^{-\beta H} \equiv \text { internal energy. }
$$

Thus

$$
k T \log \mathcal{Z}=-U+T S=-V F
$$

and hence

$$
F=-\frac{1}{\beta V} \log \mathcal{Z}
$$

$F$ is the thermodynamic potential appropriate for $T$ and $V$ as independent variables.

We are interested in the macroscopic properties of the system and so we re-express $\mathcal{Z}$ in terms of a macroscopic variable $\hat{\phi}(\mathbf{x})$. This is our "guess" for the order parameter, but it could be that it will not reveal all the possible phases of the
system. We are trying to pick out the collective coordinates on which the long-range/low-momentum physics depends. For a scalar field system this is not too difficult but when the field has internal degrees of freedom it is much harder.For example, both the phenomena of superconductivity and $\mathrm{He}_{3}$ superfluidity have spin- $\frac{1}{2}$ fundamental fields which pair to form spin-0 bosons which condense. BUT in the superconductor this pairing is in the ${ }^{1} S_{0}$ state whereas in $\mathrm{He}_{3}$ it is in the ${ }^{3} P_{0}$ state. Hence different choices must be made in these two cases.
We can choose

$$
\hat{\phi}(\mathbf{x})=\frac{1}{L^{D}} \int_{v} d \mathbf{x}^{\prime} \phi\left(\mathbf{x}^{\prime}\right),
$$

where $v$ is a volume centred at $\mathbf{x}$ with $v=L^{D} \gg a^{D}$.
Alternatively

$$
\hat{\phi}(\mathbf{x})=\int_{|\mathbf{p}| \leq \tilde{\Lambda}<\Lambda \Lambda} \frac{d^{D} p}{(2 \pi)^{D}} e^{i \mathbf{p x}} \tilde{\phi}(\mathbf{p})
$$

Here $\hat{\phi}(\mathbf{x})$ is composed of the low-momentum degrees of freedom only : $\tilde{\Lambda}=2 \pi / L$. The cut-off is now $\Lambda / L$ and hence it is possible to define the field theory for $\hat{\phi}$ on a lattice of spacing $L$. Then

$$
\begin{aligned}
e^{-\beta V F} & =\int d \phi d \hat{\phi} \delta(\hat{\phi}-\hat{\phi}(\phi)) e^{-\beta H(\phi)} \\
& =\int d \hat{\phi} e^{-\beta H(L, \hat{\phi})} .
\end{aligned}
$$

Suppose, for example,

$$
\mathcal{H}(\phi(\mathbf{x}))=\frac{1}{2}(\nabla \phi)^{2}+\frac{1}{2} m_{0}^{2} \phi^{2}+\frac{1}{4!} g_{0} \phi^{4} \ldots+\frac{1}{n!} g_{n} \phi^{n},
$$

where $n$ is taken as even and where $m_{0}^{2}, g_{n}$ are the bare or microscopic coupling constants; i.e., they parameterise field interactions on a lattice of spacing $a=$ $2 \pi / \Lambda . H(L, \phi)$ is much more appropriate to our needs since the unit of length is now $L \gg a$. Write
$\mathcal{H}(L, \hat{\phi})=\frac{1}{2} Z^{-1}(L, T)(\nabla \hat{\phi})^{2}+\frac{1}{2} m^{2}(L, T) \hat{\phi}^{2}+\frac{1}{4!} g(L, T) \hat{\phi}^{4}+\ldots+(\nabla \hat{\phi})^{4}+\ldots$
Note that the kinetic term no longer has unit coefficient. Generally at this stage it is convenient to rescale $\hat{\phi}$ to make this particular coefficient unity:

$$
\hat{\phi} \rightarrow Z^{\frac{1}{2}}(L, T) \hat{\phi}
$$

However, we will not do this rescaling for the moment.
Typically as $L$ becomes large enough

$$
Z^{-1}(L)(\nabla \hat{\phi})^{2} \sim \frac{Z^{-1}(L)}{L^{2}} \hat{\phi}^{2} \ll m^{2} \hat{\phi}^{2}
$$

Hence the effective Hamiltonian is insensitive to $\nabla \hat{\phi}$ and so $\hat{\phi}$ can be treated as a constant. Then

$$
\begin{aligned}
e^{-\beta V F} & =\int d \hat{\phi} e^{-V \beta H(\infty, \hat{\phi})}, \\
H & =\frac{1}{2} m^{2}(\infty, T) \hat{\phi}^{2}+\frac{1}{4!} g(\infty, T) \hat{\phi}^{4}+\ldots
\end{aligned}
$$

We have integrated out over all scales and produced renormalized coupling constants and an effective Hamiltonian depending on $\hat{\phi}$.
Now

$$
\begin{aligned}
\int d \mathbf{x} e^{-V S(\mathbf{x})} & =e^{-V S\left(\mathbf{x}_{0}\right)} \int d \xi e^{-V\left[\frac{1}{2} S^{\prime \prime}\left(\mathbf{x}_{0}\right) \xi^{2}+\ldots\right]} \\
& =e^{-V S\left(\mathbf{x}_{0}\right)} \int d \xi e^{-\frac{1}{2} V S^{\prime \prime}\left(\mathbf{x}_{0}\right) \xi^{2}}\left[1-\frac{1}{4!} V S^{(4)} \xi^{4}+\ldots\right] \\
& =e^{-V S\left(\mathbf{x}_{0}\right)}\left(\frac{2 \pi}{V S^{\prime \prime}}\right)^{\frac{1}{2}}\left[1-\frac{1}{4 V} \frac{S^{(4)}}{\left(S^{\prime \prime}\right)^{2}}+\ldots\right] \\
\text { where } S^{\prime}\left(\mathbf{x}_{0}\right) & =0
\end{aligned}
$$

Hence

$$
F=H\left(\infty, \hat{\phi}_{0}\right)+O\left(\frac{\log V}{V}\right)
$$

where $\hat{\phi}_{0}$ is the global minimum of $H(\infty, \hat{\phi})$. This is Landau's method with $H(\infty, \hat{\phi})$ as the free energy. function BUT this procedure requires the limit $L \rightarrow \infty$ to be under control. In particular Landau assumes that $m^{2}(\infty, T)$ is analytic in $T$. Then all that the integration over scales has done is to fix the value of $T_{c}$. This assumption is wrong for $D \leq D_{c}$ and Landau's method fails. Note that $\hat{\phi}_{0}$ is the analogue of the magnetisation: it is the order parameter and can be measured in an experiment.

Since it is the limit $L \rightarrow \infty$ which causes the trouble let us investigate calculating $F$ with $L$ finite and identify the source of the problem.
Let $S(\hat{\phi})=\beta H(L, \hat{\phi})$ and define $\hat{\phi}_{0}$ by

$$
\left(\frac{\partial S(\hat{\phi})}{\partial \hat{\phi}(\mathbf{x})}\right)_{\hat{\phi}=\hat{\phi}_{0}}=0 .
$$

Then

$$
e^{-\beta V F}=e^{-S\left(\hat{\phi}_{0}\right)} \int d \psi e^{-\frac{1}{2} S^{\prime \prime} \psi^{2}+\ldots}
$$

where

$$
S^{\prime \prime} \psi^{2} \equiv \int d \mathbf{y} d \mathbf{z}\left(\frac{\partial^{2} S}{\partial \hat{\phi}(\mathbf{y}) \hat{\phi}(\mathbf{z})}\right)_{\hat{\phi}=\hat{\phi}_{0}} \psi(\mathbf{y}) \psi(\mathbf{z})
$$

Assuming $\hat{\phi}_{0}$ is a constant independent of position and taking logs we find

$$
F=\mathcal{H}\left(L, \hat{\phi}_{0}\right)+\log \int d \psi e^{-\frac{1}{2} S^{\prime \prime} \psi^{2}+\ldots}
$$

In $\mathcal{H}$ the mass and couplings are analytic in $T$ for fixed $L$. (This is certainly plausible and is a reasonable assumption). The integral is calculated using the loop expansion. Landau assumes that these loops just change $T_{c}$ and that for $L$ large enough they may be neglected keeping only the first term in $F$ above. To illustrate how problems occur consider the effect of an external constant field $J$.

$$
H_{J}(\phi)=H(\phi)-J \int d \mathbf{x} \phi(\mathbf{x})
$$

The induced magnetisation is

$$
<\phi>_{J}=\frac{1}{\mathcal{Z}_{J}} \int d \phi \phi(0) e^{-\beta H_{J}(\phi)}
$$

and the susceptibilty is

$$
\chi=\left(\frac{\partial<\phi>_{J}}{\partial J}\right)_{J=0}=\beta \int d \mathbf{x}<\phi(0) \phi(\mathbf{x})>_{c}
$$

That is, the integral over the connected two-point function

$$
<\phi(0) \phi(\mathbf{x})>_{c}=<\phi(0) \phi(\mathbf{x})>-<\phi(0)><\phi(\mathbf{x})>.
$$

The second term arises from differentiation of $\mathcal{Z}_{J}$ in the denominator. We now define the smoothed field $\hat{\phi}(L, x)$ including a renormalization to keep the coefficient of $\frac{1}{2}(\nabla \phi)^{2}$ in $H(L, \hat{\phi})$ to be unity. Of course, we must remember this rescaling if we re-express results in terms of the actual magnetisation. Then

$$
\begin{aligned}
\hat{\phi}(\mathbf{x}) & =\frac{Z_{1}^{-\frac{1}{2}}(L)}{L^{D}} \int_{L} d \mathbf{x}^{\prime} \phi\left(\mathbf{x}^{\prime}\right), \\
\chi & =\beta Z_{1}(L) \int d \mathbf{x}<\hat{\phi}(0) \hat{\phi}(\mathbf{x})>_{c} .
\end{aligned}
$$

We define

$$
\begin{aligned}
& \hat{\mathcal{G}}_{L}(\mathbf{p})=\int d \mathbf{x}<\hat{\phi}(0) \hat{\phi}(\mathbf{x})>_{c} e^{-i \mathbf{p x}} \\
& \hat{\Gamma}_{L}(\mathbf{p})=\hat{\mathcal{G}}_{L}(\mathbf{p})^{-1}
\end{aligned}
$$

## $\hat{\Gamma}_{L}$ is the truncated two-point function.

[ In general, the n-point function $G_{n}\left(\mathbf{p}_{1}, \ldots, \mathbf{p}_{n}\right)$ is defined by

$$
G_{n}\left(\mathbf{p}_{1}, \ldots, \mathbf{p}_{n}\right)=\int d \mathbf{x}_{1} \ldots d \mathbf{x}_{n}<\phi\left(\mathbf{x}_{1}\right) \phi\left(\mathbf{x}_{2}\right) \ldots \phi\left(\mathbf{x}_{n}\right)>_{c} e^{-i \mathbf{p}_{i} \cdot \mathbf{x}_{i}}
$$

and the truncated n-point function is defined by

$$
\Gamma_{n}\left(\mathbf{p}_{1}, \ldots, \mathbf{p}_{n}\right)=\frac{G_{n}\left(\mathbf{p}_{1}, \ldots, \mathbf{p}_{n}\right)}{G\left(\mathbf{p}_{1}\right) G\left(\mathbf{p}_{2}\right) \ldots G\left(\mathbf{p}_{n}\right)}
$$

$G_{n}$ contains the denominator of the RHS as a factor and $\Gamma_{n}$ is often a more useful quantity with which to work.]
Then we have

$$
\chi^{-1}=\frac{1}{\beta \mathcal{Z}_{1}(L)} \hat{\Gamma}_{L}(0)
$$

From now on we will absorb a factor of $\beta^{\frac{1}{2}}$ into $\hat{\phi}$, i.e., replace

$$
\hat{\phi} \rightarrow \beta^{-\frac{1}{2}} \hat{\phi} .
$$

then $m^{2} \rightarrow m^{2}, g \rightarrow \beta g$ etc. and

$$
\chi^{-1}=\frac{\hat{\Gamma}_{L}(0)}{\mathcal{Z}_{1}(L)} .
$$

To calculate $\hat{\Gamma}_{L}$ we need to use perturbation theory.

### 4.1 The Perturbation Expansion

We start with the definition

$$
<\phi(0) \phi(\mathbf{x})>=\frac{1}{\mathcal{Z}} \int d \phi \phi(0) \phi(\mathbf{x}) e^{-S(\phi)} .
$$

Let

$$
S(\phi)=\int d \mathbf{x} \frac{1}{2}(\nabla \phi)^{2}+\frac{1}{2} m^{2} \phi^{2}+\frac{1}{4!} g \phi^{4}
$$

where $m^{2}$ can be negative. The situation $m^{2}<0$ corresponds to spontaneous breaking of the symmetry $\phi \rightarrow-\phi$ in the bare Hamiltonian. However, we shall see that the effective mass is positive once loop corrections are included.
In order to be able to perform the loop expansion we write

$$
\begin{aligned}
S(\phi) & =\int d \mathbf{x} \frac{1}{2}(\nabla \phi)^{2}+\frac{1}{2} \mu^{2} \phi^{2}+\frac{1}{2}\left(m^{2}-\mu^{2}\right) \phi^{2}+\frac{1}{4!} g \phi^{4} \\
S_{0}(\phi) & =\int d \mathbf{x} \frac{1}{2}(\nabla \phi)^{2}+\frac{1}{2} \mu^{2} \phi^{2},
\end{aligned}
$$

and choose $\mu^{2}>0$.
Then with

$$
\mathcal{Z}=\int d \phi e^{-S_{0}(\phi)} e^{-\int d \mathbf{x} \frac{1}{2}\left(m^{2}-\mu^{2}\right) \phi^{2}+\frac{1}{4!g \phi^{4}}}
$$

we have

$$
\begin{aligned}
<\phi(0) \phi(\mathbf{x})> & \\
& =\frac{1}{\mathcal{Z}} \int d \phi \phi(0) \phi(\mathbf{x}) e^{-S_{0}(\phi)} e^{-\int d \mathbf{x} \frac{1}{2}\left(m^{2}-\mu^{2}\right) \phi^{2}+\frac{1}{4!} g \phi^{4}} \\
& =\frac{1}{\mathcal{Z}} \int d \phi \phi(0) \phi(\mathbf{x})\left[1-\int d \mathbf{x} \frac{1}{2}\left(m^{2}-\mu^{2}\right) \phi^{2}+\frac{1}{4!} g \phi^{4}+\ldots\right] e^{S_{0}(\phi)}
\end{aligned}
$$

This consists of a sequence of gaussian integrals which are best done in momentum space. they take the form

$$
\begin{array}{r}
\int d \phi e^{-\int d \mathbf{y} d \mathbf{z} \phi(\mathbf{y}) Q(\mathbf{y}-\mathbf{z}) \phi(\mathbf{z})} \phi(0) \phi(\mathbf{x}) \\
=A(\operatorname{det} Q)^{-\frac{1}{2}} Q^{-1}(x)
\end{array}
$$

and

$$
\begin{array}{r}
\int d \phi e^{-\int \phi Q \phi} \phi(0) \phi(\mathbf{x}) \int d \mathbf{z} g \phi^{4}(\mathbf{z}) \\
=g B(\operatorname{det} Q)^{-\frac{1}{2}} \int d \mathbf{z} Q^{-1}(\mathbf{z}) Q^{-1}(\mathbf{x}-\mathbf{z}) Q^{-1}(0) .
\end{array}
$$

The denominator cancels the $(\operatorname{det} Q)^{-\frac{1}{2}}$ leaving a calculable combinatorial coefficient. In momentum space we have the diagram expansion as follows

$$
\begin{aligned}
G(\mathbf{p}) & =\int d \mathbf{x}<\phi(0) \phi(\mathbf{x})>_{c} e^{-i \mathbf{p x}} \\
& =\tilde{Q}^{-1}(\mathbf{p})-\tilde{Q}^{-1}(\mathbf{p})\left(m^{2}-\mu^{2}\right) \tilde{Q}^{-1}(\mathbf{p})-C g \tilde{Q}^{-1}(\mathbf{p}) \int \frac{d^{D} q}{(2 \pi)^{D}} \tilde{Q}^{-1}(\mathbf{q}) \tilde{Q}^{-1}(\mathbf{p})+\ldots
\end{aligned}
$$

or

$$
\Gamma(\mathbf{p})=\tilde{Q}^{-1}(\mathbf{p})+\left(m^{2}-\mu^{2}\right)+C g \int \frac{d^{D} q}{(2 \pi)^{D}} \tilde{Q}^{-1}(\mathbf{q})+\ldots
$$

$\tilde{Q}^{-1}(\mathbf{p})$ is the bare Feynman propagator: $\tilde{Q}^{-1}(\mathbf{p})=\left(\mathbf{p}^{2}+\mu^{2}\right)^{-1}$.
Then

The expansion shown for $\Gamma$ is exact to $O(g)$ but corresponds to a sum over selected 1-particle irreducible graphs in $G$. this can be seen as follows.

$$
G=\frac{1}{\Gamma}=\frac{1}{Q+\delta m^{2}+\Sigma},
$$

where $\Sigma$ represents 1-particle irreducible (1PI) diagrams. This means that
they cannot be separated into two pieces by cutting one line only. E.g., Expand

PR
the above expression to give

$$
\begin{aligned}
G=\frac{1}{Q} & -\frac{1}{Q}\left(\delta m^{2}+\Sigma\right) \frac{1}{Q} \\
& +\frac{1}{Q}\left(\delta m^{2}+\Sigma\right) \frac{1}{Q}\left(\delta m^{2}+\Sigma\right) \frac{1}{Q}+\ldots
\end{aligned}
$$

Diagramatically we have

To $O(g)$ :

Note that $\Gamma$ is truncated because it contains no propagator factors, $\tilde{Q}^{-1}$, for external legs.

The expansion for $\Gamma(\mathbf{p})$ can be improved by summing over all bubble insertions on the internal loop. Then

$$
\Gamma(\mathrm{p})=(\longrightarrow)^{-1}=\mathrm{p}^{2}+\mathrm{m}^{2}+\mathrm{Cg} \longrightarrow+\ldots \ldots
$$

The Feynman rules for constructing the diagrams are

$$
\begin{array}{lc}
\frac{1}{\mathbf{p}^{2}+m^{2}} & \text { for each propagator line } \\
\int \frac{d^{D} q}{(2 \pi)^{D}} & \text { for each closed loop } \\
\delta^{D}\left(\sum \mathbf{p}_{i}\right) & \text { momemtum conservation at each vertex }
\end{array}
$$

$$
\text { factor } \quad C=\frac{1}{S}
$$

Where $S$ is the number of symmetry operations that leave the graph unchanged, for example

Note that disconnected contributions to the numerator, e.g.,

are cancelled by terms in the denominator. Hence, only get connected graphs for expansion of $G$. For our smoothed theory we have

$$
m^{2} \equiv m^{2}(L, T)
$$

Remember that $m^{2}$ is not necessarily positive. Then

$$
=\frac{Z_{L}\left(\mathbf{p}^{2}, T\right)}{\mathbf{p}^{2}+m^{2}(\infty, T)} .
$$

Here $m^{2}(\infty, T)=\xi^{-2}(T)$ and is positive. The loop correction renormalizes $m^{2}$ additively and the resulting effective mass is positive. Now

$$
\chi^{-1}=\frac{\hat{\Gamma}_{L}(0)}{Z_{1}(L)}=\frac{m^{2}(\infty, T)}{Z_{1}(L) Z_{L}(0, T)}
$$

$\chi^{-1}$ vanishes at $T=T_{0}$ which is given by the vanishing of the renormalized mass:

$$
\lim _{T \rightarrow T_{c}} m^{2}(\infty, T)=0
$$

Note that in general $\lim _{T \rightarrow T_{c}} Z_{L}(0, T)=0$ as well but that the numerator dominates. In fact for our present discussion

$$
Z_{L}=1+O\left(g^{2}\right),
$$

and hence to $O(g) Z_{L}=1$.
Then

$$
m^{2}(\infty, T)=m^{2}(L, T)+\frac{1}{2} g \int \frac{d^{D} p}{(2 \pi)^{D}} \frac{1}{\mathbf{p}^{2}+m^{2}(\infty, T)}+\ldots
$$

Note that the bubble summation removed all reference to $\mu^{2}$. In fact we can see that by choosing $\mu^{2}=m^{2}(\infty, T)$ in the first place we automatically get the improved formula from the one-loop expression. the coefficient of $\frac{1}{2}$ comes from the symmetry factor as described above. Using $m^{2}\left(\infty, T_{c}\right)=0$ we write

$$
\begin{aligned}
m^{2}(\infty, T) & =m^{2}(L, T)-m^{2}\left(L, T_{c}\right)+\frac{1}{2} g \int^{\frac{2 \pi}{L}} \frac{d^{D} p}{(2 \pi)^{D}}\left[\frac{1}{\mathbf{p}^{2}+m^{2}(\infty, T)}-\frac{1}{\mathbf{p}^{2}}\right] \\
& =A t-\frac{1}{2} g m^{2}(\infty, T) \int^{\frac{2 \pi}{L}} \frac{d^{D} p}{(2 \pi)^{D}} \frac{1}{\left(\mathbf{p}^{2}+m^{2}(\infty, T)\right) \mathbf{p}^{2}}+\ldots
\end{aligned}
$$

Where $t=\left(T-T_{c}\right) / T_{c}$.
We consider two cases:
$D>4$ The integral is dominated by large $\mathbf{p}$ and is finite in the limit $m^{2} \rightarrow 0$. Then

$$
m^{2}(\infty, T)=A t+B m^{2}(\infty, T)
$$

This is consistent with the Landau behaviour

$$
m^{2}(\infty, T)=C t
$$

$D<4$ The integral is sensitive to low $\mathbf{p}$ and is Infra-Red divergent unless $m^{2}>$ 0 :

$$
m^{2}(\infty, T)=A t+B m^{D-2}(\infty, T)
$$

This is clearly inconsistent with the Landau assumption: the integral is important. IR divergences invalidate Landau's assumption.
$D=4$ A marginal case with IR logarithmic corrections

$$
m^{2}(\infty, T)=A t+B m^{2} \log m^{2}
$$

Get Landau behaviour modified by logs.

Hence $D_{c}=4$ and for $D \leq 4$ IR effects destroy mean-field predictions.
This theory applies to an ordinary critical point in Landau's theory: the coefficient of $\phi^{2}$ vanishes. If, for some reason, the $\phi^{4}$ were absent and the interaction started at the $g \phi^{6}$ term then the loop contribution would be

$$
\sim \int^{\frac{2 \pi}{L}} \frac{d^{D} p}{(2 \pi)^{D}} \frac{1}{\mathbf{p}^{2}+m^{2}(\infty, T)} \int^{\frac{2 \pi}{L}} \frac{d^{D} q}{(2 \pi)^{D}} \frac{1}{\mathbf{q}^{2}+m^{2}(\infty, T)} .
$$

Subtracting off the value at $m^{2}=0$ and isolating the most IR divergent integral gives

$$
\int^{\frac{2 \pi}{L}} \frac{d^{D} p}{(2 \pi)^{D}} \int^{\frac{2 \pi}{L}} \frac{d^{D} q}{(2 \pi)^{D}} \frac{1}{\mathbf{p}^{2}\left(\mathbf{p}^{2}+m^{2}(\infty, T)\right)\left(\mathbf{q}^{2}+m^{2}(\infty, T)\right)}
$$

There are no IR problems for $2 D-6>0$, i.e., $D>3$. Hence in this case $D_{c}=3$. In Landau's theory this situation corresponds to a tricritical point: the coefficients of $\phi^{2}$ and $\phi^{4}$ vanish.
In general, for interaction $\phi^{2 n}$ we find

$$
(n-1) D_{c}-2 n=0,
$$

or

$$
D_{c}=\frac{2 n}{n-1} .
$$

This interaction is relevant only for critical points of order $n$. For $D=2$ all critical points show anomalous behaviour but for $D=3$ only critical and tricritical points are anomalous, and even then the corrections to mean-field predictions at the tricritical point are only logarithmic.

It is important to understand heuristically or phenomenologically what is happening before actually doing detailed calculations. First we define the correlation length, $\xi$, a bit more explicitly than before.
For $x \gg a$

$$
<\phi(0) \phi(\mathbf{x})>_{c} \sim e^{-|\mathbf{x}| / \xi}
$$

In fact if $\mathbf{x}=\left(x_{0}, \ldots, x_{D-1}\right)$ then

$$
\int d x_{1} \ldots d x_{D-1}<\phi(0) \phi(\mathbf{x})>_{c} \rightarrow C e^{-x_{0} / \xi}
$$

as $x_{0}$ becomes large. This is how we might calculate $\xi$ on a computer. [ Note

$$
\int d \mathbf{p} \frac{e^{i \mathbf{p} \mathbf{x}}}{\mathbf{p}^{2}+m^{2}}=A e^{-m|\mathbf{x}|}
$$

]
Now, $\hat{\phi}(L)$ averages $\phi$ over blocks of size $L^{D}$, but if $D \leq D_{c} M(L)=Z_{1}^{\frac{1}{2}}(L) \hat{\phi}(L)$ cannot be identified with the magnetisation of the bulk volume, $V$, since there are still fluctuations in the system of wavelengths greater than $L$ which cause these blocks to interact. In other words a block of size $L^{D}$ is not big enough to be a good model of a larger system. Only for $L \gg \xi$ will this be true. For $D \leq D_{c}$ there are important fluctuations on all scales $L<\xi$, and only for $D>D_{c}$ are these fluctuations suppressed and Landau's theory works.
(1) In the theory with $L=\xi$ we do not expect significant loop corrections.

Hence

$$
<\phi(0) \phi(\mathbf{x})>_{c} \sim e^{-m(\xi, T)|\mathbf{x}|},
$$

which identifies $\xi^{-1}=m(\xi, T)$.
If we postulate that $m(\xi, T) \sim \xi^{\sigma} \cdot\left(T-T_{c}\right)$, then we find

$$
\xi \sim t^{-\nu}, \quad \nu=\frac{1}{1+\sigma} .
$$

Also

$$
\chi^{-1}=\Gamma(\mathbf{p}=0) \sim \frac{1}{Z_{1}(\xi)} m^{2}(\xi, T)
$$

Then if $Z_{1}(\xi) \sim \xi^{\rho} \equiv m^{-\rho}$ we get

$$
\chi \sim t^{-\alpha}, \quad \alpha=\nu(\rho+2)
$$

(2) In general we have

$$
\begin{aligned}
G(\mathbf{x}) & \equiv<\phi(0) \phi(\mathbf{x})>_{c} & & \\
& =C(a) \frac{\xi^{\rho}}{(|\mathbf{x}| \xi)^{(D-1) / 2}} e^{-|\mathbf{x}| / \xi}, & & a \ll \xi \ll|\mathbf{x}| \\
& =C^{\prime}(a) \frac{1}{|\mathbf{x}|^{2 \Delta_{\phi}}}, \quad \Delta_{\phi}=(D-1-\rho) / 2, & & a \ll|\mathbf{x}| \ll \xi
\end{aligned}
$$

where $A$ is the lattice spacing, i.e., $\Lambda=2 \pi / a$ is the UV cut- off. In all we do $\Lambda$ is finite but $\Lambda \gg m$ and for all momenta $\mathbf{p}$ of interest $\Lambda \gg|\mathbf{p}|$ (i.e., $a \ll|\mathbf{x}|)$. Hence we are always working in the limit of very large cut-off.
(a) It is important to realise that $\xi$ sets the scale and not $a$, otherwise the correlators would be badly behaved as $\xi / a \rightarrow \infty$ and/or $|\mathbf{x}| / a \rightarrow \infty$. This is the basic assumption of the scaling hypothesis.
(b) "Naive" dimensional analysis must work.

$$
\left[\int d \mathbf{x}(\nabla \phi)^{2}\right]=0 \Rightarrow[\phi]=\frac{1}{2}(D-2) .
$$

Where [] signifies the dimension of the enclosed quantity in units of momentum. Hence

$$
[\langle\phi \phi\rangle]=D-2 .
$$

Thus in the above expression for $G(\mathbf{x})$ we must have

$$
C(a) \sim a^{2 \eta}, \quad \eta=\Delta_{\phi}-\frac{1}{2}(D-2)
$$

$\eta$ is the anomalous dimension of the field $\phi$, and $\Delta_{\phi}$ is the scaling dimension of $\phi$.

Now

$$
\begin{aligned}
\chi & =\int d \mathbf{x} G(\mathbf{x}) \sim \int d \mathbf{x} \frac{e^{-|\mathbf{x}| / \xi}}{|\mathbf{x}|^{2 \Delta_{\phi}}} \\
\Rightarrow \chi & \sim \xi^{D-2 \Delta_{\phi}} .
\end{aligned}
$$

Comparing with the alternative expression for the behaviour of $\xi$ in (1) above we find the scaling relation

$$
\alpha=\nu\left(D-2 \Delta_{\phi}\right) .
$$

(3) The results of (2) can be seen in a different way. We have the general parametrization

$$
G(\mathbf{p})=\frac{Z(\mathbf{p}, \xi)}{\mathbf{p}^{2}+m^{2}(\xi, T)}
$$

We were concerned with $\mathbf{p}=0$ earlier $(\chi=G(\mathbf{p}=0)$ ), but now instead consider $\Lambda \gg|\mathbf{p}| \gg m$. Because $Z$ is dimensionless we have

$$
Z \sim(a p)^{-\rho^{\prime}} f\left(\frac{m}{p}\right) \quad p \gg m \equiv \xi^{-1}
$$

where $p \equiv \mathbf{p}$. Also from above in (1) we have

$$
Z \sim(a m)^{-\rho} g\left(\frac{p}{m}\right) \quad p \ll m \equiv \xi^{-1}
$$

This is because $Z \sim Z_{1}(\xi) \sim \xi^{\rho}$ for $p=0$.
Note that $f$ and $g$ do not depend explicitly on (ap) or (am) for the reasons outlined in (2a) above: because of the scaling hypothesis. Then
(a) $Z(p=0, m)$ is non-zero and finite for $m \neq 0$.
$Z(p, m=0)$ is non-zero and finite for $p \neq 0$.
(b) the scaling hypothesis asserts that $m$ (i.e. $\xi$ ) sets the scale and not $\Lambda$ (i.e. not $a$ ). Hence the above scaling forms must be valid with $f(0)$ and $g(0)$ non-zero and finite. It then follows that

$$
\begin{aligned}
\rho & =\rho^{\prime} \\
g(z) & =\left(\frac{1}{z}\right)^{\rho} f\left(\frac{1}{z}\right) .
\end{aligned}
$$

By comparing powers of $a$ we also get

$$
\rho=-2 \eta .
$$

Substituting $\rho$ in terms of $\alpha$ from part (1) gives the scaling relation derived in (2).

The important thing to notice in all of this is that each quantity in which we are interested depends on $a$ in a simple and special way. Namely, $a$ appears raised to a power as a multiplicative factor only: $a$ does not appear as part of an argument of any of the functions. These function depend only on the long range observables. Since $a$ has dimensions it follows that whilst "naive" dimensional analysis holds when including the factor depending on $a$, the dimension of the function it multiplies is not constrained. This means that if we concentrate on the dimensions of this function (e.g., $f$ or $g$ above) the contributions to its dimension from the observable quantities can add up to something other than the "naive" dimension, i.e. the anomalous dimension. Since, in any given system $a$ is fixed the anomalous dimension is the most natural dimension with which to be concerned. After all, we can vary $\xi$ by varying $T$ but $a$ is, of course, unchanged. It is the object of most analyses of critical phenomena to calculate these anomalous dimensions.

### 4.2 The Effective Potential and the Legendre Transform

Consider the partition function in the presence of an external source J :

$$
\mathcal{Z}(J)=\int d \phi e^{-S(\phi)+J \phi} .
$$

Denote $S(\phi, J)=S(\phi)-J \phi$.
Then

$$
\mathcal{Z}(J)=e^{-S(\phi(J), J)} \int d \psi e^{-\frac{1}{2} S_{J}^{(2)} \psi^{2}+\ldots}
$$

where

$$
\left(\frac{\delta S}{\delta \phi}\right)(\phi, J)=0 \text { when } \phi=\phi(J) \equiv \phi(\mathbf{x} ; J)
$$

and

$$
\begin{aligned}
S_{J}^{(2)} \psi^{2} & =\int d \mathbf{y} d \mathbf{z}\left(\frac{\delta^{2} S}{\delta \phi(\mathbf{y}) \delta \phi(\mathbf{z})}\right)_{\phi=\phi(J)} \psi(\mathbf{y}) \psi(\mathbf{z}) \\
\psi(\mathbf{y}) & =\phi(\mathbf{y})-\phi(\mathbf{y} ; J)
\end{aligned}
$$

Space arguments will be suppressed wherever possible.
Thus

$$
\log \mathcal{Z}(J)=-S(\phi(J), J)+\log \int d \psi e^{-\frac{1}{2} S_{J}^{(2)} \psi^{2}+\ldots}
$$

The integral generates loop corrections: this is the loop expansion. It is essentially the same as the perturbation expansion we saw before except that here the expansion is about the minimum of $S(\phi, J)$. Then we have terms of the form

$$
\begin{aligned}
\int d \psi e^{-\frac{1}{2} S_{J}^{(2)} \psi^{2}} e^{-\frac{1}{3!} S^{(3)}(J) \psi^{3}-\ldots} & =\int d \psi e^{-\frac{1}{2} S_{J}^{(2)} \psi^{2}}\left(1-\frac{1}{3!} S^{(3)}(J) \psi^{3}-\ldots\right) \\
& =A\left[\operatorname{det}\left(S_{J}^{(2)}\right)\right]^{-\frac{1}{2}}(1+\ldots) .
\end{aligned}
$$

We get a set of gaussian integrals which generate the loops. For example, the 1-loop contribution to $\log \mathcal{Z}(J)$ is

$$
-\frac{1}{2}\left[\operatorname{det}\left(S_{J}^{(2)}\right)\right]
$$

In general

$$
<\phi\left(\mathbf{x}_{1}\right) \ldots \phi\left(\mathbf{x}_{n}\right)>_{c}=\left(\frac{\delta^{n} \log \mathcal{Z}(J)}{\delta J\left(\mathbf{x}_{1}\right) \ldots \delta J\left(\mathbf{x}_{n}\right)}\right)_{J=0}
$$

(See problem sheet 2a for an explicit example of the 1-loop calculation.)
The tree diagrams are generated by $-S(\phi(J), J)$. Once we understand how this works we can verify the preceding statements. Consider the approximation

$$
W(J) \equiv \log \mathcal{Z}(J) \approx W_{T}(J)=-S(\phi(J), J) .
$$

$\phi(J)$ satisfies

$$
\left(\frac{\delta S}{\delta \phi}\right)_{\phi=\phi(J)}=0
$$

This is the field equation and $\phi(J)$ is the classical solution. Then

$$
\begin{aligned}
\frac{\delta W_{T}(J)}{\delta J} & =-\frac{\delta S}{\delta \phi(J)} \frac{\delta \phi(J)}{\delta J}+J \frac{\delta \phi(J)}{\delta J}+\phi(J) \\
& =\phi(J)
\end{aligned}
$$

This field equation is explicitly of the form

$$
\left(-\nabla^{2}+m^{2}\right) \phi(\mathbf{x} ; J)+\frac{1}{6} g \phi^{3}(\mathbf{x} ; J)=J(\mathbf{x}) .
$$

Clearly all derivatives of $W$ with respect to $J$ can be generated from the previous equation once this classical equation has been solved. In perturbation theory we have, in momemtum space

$$
\phi(\mathbf{p} ; J)=\frac{J(\mathbf{p})}{\mathbf{p}^{2}+m^{2}}-\frac{g}{6\left(\mathbf{p}^{2}+m^{2}\right)} \int d \mathbf{x} \phi^{3}(\mathbf{x} ; J) e^{-i \mathbf{p x}}
$$

Or, diagramatically

Iterating this equation gives

All momenta are integrated with momentum conserved at each vertex. This is just the tree expansion of $W(J)$. It is generated by the classical field solution, $\phi(J)$ : i.e., there are no $\hbar$ factors.
E.g.,

$$
\left(\frac{\delta^{4} W_{T}(J)}{\delta J(\mathbf{p}) \delta J\left(\mathbf{q}_{1}\right) \delta J\left(\mathbf{q}_{2}\right) \delta J\left(\mathbf{q}_{3}\right)}\right)_{J=0}=g \delta^{4}\left(\mathbf{p}+\mathbf{q}_{1}+\mathbf{q}_{2}+\mathbf{q}_{3}\right),
$$

This is the tree contribution to the 4 -point vertex.
Now, two important points
(1) If $W_{T}(J)$ is the tree approximation to $W(J)$ as outlined above, then $W_{T}(J)$ is the Legendre transform of $S(\phi)$. That is, it follows directly from the above discussion that

$$
W_{T}(J)=\max _{\phi}(J \phi-S(\phi)),
$$

which is the Legendre transform of $S \phi$ ).
Then define

$$
S_{H}(\phi)=\max _{J}\left(J \phi-W_{T}(J)\right) .
$$

Clearly $S_{H}(\phi)$ is not a function of $J$, i.e.,

$$
\frac{\partial S_{H}}{\partial J}=0 .
$$

If $S(\phi)$ is convex then $S_{H}(\phi)=S(\phi)$, otherwise $S_{H}(\phi)$ is the convex hull of $S(\phi)$ :

This subtlety has a lot to do with the Maxwell construction and domains associated with a first order transition. It applies to a complete study of the symmetry broken phase but we shall not pursue it further here.
(2) For $\phi=M$, a constant, $S(M)$ was the effective potential which is minimised to give Landau's approximation to the free energy. Remember the form of $S(M)$ with an assumption of analyticity of the coefficients in $T$ is what was needed: loops just modify $T_{c}$. Hence Landau's method is classical: it corresponds in form to tree diagrams. In general, $S_{H}(\phi)$ is the effective action of the classical or Landau theory. Note that $S(\phi)$ is exactly the action which appears in the expression for $\mathcal{Z}$

$$
\mathcal{Z}=\int d \phi e^{-S(\phi)} .
$$

That is, this $S(\phi)$ is the Legendre transform of $W_{T}(J)$. There are some niceties concerning whether one should use $S$ or $S_{H}$ here, but we will not discuss this further.
$W(J)$ generates the connected diagrams. Then schematically it must have the diagramatic form

$$
W(J)=
$$

trees

The vertices of the trees are the 1PI diagrams of the theory, i.e., they contain sums over all loop contributions but thay cannot be separated into two disjoint pieces by cutting one line only.
We can generate these tree diagrams with an appropriately chosen effective action. This is the effective action of the full theory. It is the Legendre transform of $W(J)$ :

$$
\begin{aligned}
S_{E}(\phi) & =\max _{J}(J \phi-W(J)) \\
S_{E}(\phi) & =\sum_{n} \frac{1}{n!} \int d \mathbf{x}_{1} \ldots d \mathbf{x}_{n} \Gamma_{n}\left(\mathbf{x}_{1} \ldots \mathbf{x}_{n}\right) \phi\left(\mathbf{x}_{1}\right) \ldots \phi\left(\mathbf{x}_{n}\right) .
\end{aligned}
$$

Hence $S_{E}(\phi)$ generates the 1PI diagrams of the theory.
$S_{E}(\phi)$ is now treated as a classical action since it is all that is needed to generate the whole theory by its tree expansion. The equilibrium free energy is

$$
F=\frac{-W(0)}{\beta V},
$$

and

$$
\begin{aligned}
W(0) & =\max _{\phi}\left(J \phi-S_{E}(\phi)\right)_{J=0} \\
& =\max _{\phi}\left(-S_{E}(\phi)\right)
\end{aligned}
$$

Hence the free energy function $F(\phi)$ is identified as

$$
F(\phi)=\frac{1}{\beta V} S_{E}(\phi)
$$

and equilibrium corresponds to minimising $F(\phi)$ with respect to $\phi$. This is like the Landau method but we cannot assume that the effective coupling constants in $S_{E}$ are analytic in $T$ : they are only for $D>D_{c}$.
Note
(1) $S_{E}(\phi)$ is always convex and, in fact, is the correct effective action describing the system for all phases.
(2) If $J$ is a constant function then the magnetisation is given by

$$
\begin{aligned}
M & =\frac{d W}{d J} \Rightarrow \\
\phi(J) & =M
\end{aligned}
$$

In general, $J(\mathbf{x})$ and $M(\mathbf{x})=\frac{d W}{d J(\mathbf{x})}$ are conjugate variables. This is also shown by how they appear in the Legendre transformation. This is, of course, the same relationship that they have in thermodynamics.

### 4.3 The Ising model

The Hamiltonian is given by

$$
-\beta H=S_{i} V_{i j} S_{j}+J_{i} S_{i}
$$

$S_{i}$ is that variable at the $i$-th site with $S_{i}= \pm 1 . J_{i}$ is the external field and $V_{i j}$ contains the couplings between neighbours: it need not be nearest neighbour. Introduce $X_{i} \in \mathcal{R}$ and note the identity

$$
\begin{array}{r}
\int \prod d X_{i} e^{-\frac{1}{4} X_{i} V_{i j}^{-1} X_{j}+S_{i} X_{i}} \\
=\text { Const } \cdot e^{S_{i} V_{i j} S_{j}} .
\end{array}
$$

Then

$$
\mathcal{Z}(J)=\sum_{S_{i}} \int \prod d X_{i} e^{-\frac{1}{4}\left(X_{i}-J_{i}\right) V_{i j}^{-1}\left(X_{j}-J_{j}\right)+S_{i} X_{i}}
$$

Now sum on $S_{i}$

$$
\sum_{S= \pm 1} e^{S X}=2 e^{(\log \cosh X)} \equiv 2 e^{A(X)}
$$

Hence, ignoring all irrelevant multiplicative constants

$$
\mathcal{Z}(J)=\int \prod d X_{i} e^{\left.-\frac{1}{4}\left(X_{i}-J_{i}\right) V_{i j}^{-1} X_{j}-J_{j}\right)+\sum_{i} A\left(X_{i}\right)}
$$

We calculate the free energy by steepest descent (i.e. by expanding about the minimum of the exponent as we have done before) and keeping only the first term
is equivalent to Landau theory: that is, to the tree approximation. Minimising the action gives

$$
\frac{1}{2} V_{i j}^{-1}\left(\bar{X}_{j}-J_{j}\right)=\frac{\left.\partial A\left(\overline{( } X_{i}\right)\right)}{\partial X_{i}}
$$

This defines $\bar{X}_{i}$ which minimises the action. Thus in this approximation

$$
\begin{aligned}
W_{T}(J) & =\log \mathcal{Z}(J) \\
& =\frac{1}{4}\left(\bar{X}_{i}-J_{i}\right) V_{i j}^{-1}\left(\bar{X}_{j}-J_{j}\right)+\sum_{i} A\left(\bar{X}_{i}\right)
\end{aligned}
$$

But

$$
\begin{aligned}
M_{i} & =\frac{\delta \log \mathcal{Z}(J)}{\delta J_{i}} \\
& =-\frac{1}{2} V_{i j}^{-1}\left(\bar{X}_{j}-J_{j}\right)
\end{aligned}
$$

and using the defining equation for $\bar{X}$ above we get

$$
M_{i}=\frac{\delta A}{\delta X_{i}}\left(\bar{X}_{i}\right)=\tanh \left(\bar{X}_{i}\right)
$$

(Remember, $\bar{X}$ and $M$ are both functions of $J$.)
To find the free energy function $F(M)$ we take the Legendre transform of $W_{T}(J)$

$$
-\beta N F(M)=\max _{J}\left(\mathbf{J} \cdot \mathbf{M}-W_{T}(J)\right)
$$

where $N$ is the number of sites. Then
$\beta N F(M)=-V_{i j} M_{i} M_{j}+\frac{1}{2} \sum_{i}\left[\left(1+M_{i}\right) \log \left(1+M_{i}\right)+\left(1-M_{i}\right) \log \left(1-M_{i}\right)\right]$.
Note that $\beta N F(M)$ in this approximation is the correct quantum action to be used in the full theory which includes all loops. This is because it defines the tree diagrams of the theory and hence gives all the bare vertices. the loops are built up in the usual way from these vertices.
For constant magnetisation $M_{i}=M$ and $M$ small

$$
\beta F(M)=-V M^{2}+\frac{(1+M)}{2}\left(\left(M-\frac{M^{2}}{2}+\frac{M^{3}}{3}+\ldots\right)+\frac{(1-M)}{2}\left(\left(-M-\frac{M^{2}}{2}-\frac{M^{3}}{3}+\ldots\right) .\right.\right.
$$

$F$ is the free energy per site and $V=\sum_{j} V_{0 j}$. Then

$$
\beta F(M)=\left(\frac{1}{2}-V\right) M^{2}+\frac{1}{12} M^{4}+\ldots
$$

Since $V=V(\beta)$ we have a second order transition at $\beta=\beta_{c}$ given by $V\left(\beta_{c}\right)=\frac{1}{2}$.
In the simplest case

$$
V_{i j}=\beta \kappa_{i j \Rightarrow} \quad \beta_{c}=\frac{1}{2 \kappa}, \quad \kappa=\sum_{j} \kappa_{0 j} .
$$

Notes
(1) This is the mean-field approximation and we know that the critical exponents are analytic only correct for $D>D_{c}$.
(2) The external field method together with the Legendre transform enabled us to calculate the free energy as a function of the relevant order parameter, M. Near the transition the Ising model can be described by a scalar field theory with the full theory based on the action $F(\phi)$. $F$ is the function defined above by $F(\mathbf{M})$ for general (i.e. not constant) $\mathbf{M}(\phi$ is identified with $\mathbf{M}$ to make the correspondence clear). Thus we have found the action for a scalar field theory which is, in every way, equivalent to the Ising model near a continuous phase transition. This is the phenomenon of universality.
Universality: many models which have disparate descriptions on the microscopic scale exhibit the same critical properties with the same critical exponents. Near critical points these models are descibed by the same field theory and belong to the same universality class. Here we have found that the Ising model and scalar field theory belong to the same universality class.
(3) Even for $D>D_{c}$ loop contributions will give corrections to $\beta_{c}$. The 1-loop correction to the tree-level effective action is given by $\frac{1}{2} \operatorname{det} F^{(2)}(\phi)$. This contribution is the subject of example sheet 2 a .

### 4.4 Calculation of the Critical Index

This section is concerned with the calculation of the critical index $\nu$ in the Ising model. We work with $\phi^{4}$ field theory in $D$ dimensions.

$$
\begin{aligned}
S(\phi) & =\int d \mathbf{x} \frac{1}{2}(\nabla \phi)^{2}+\frac{1}{2} m^{2} \phi^{2}+\frac{1}{4!} g \phi^{4}+\ldots \\
{\left[m^{2}\right] } & =2 \quad[g]=4-D \equiv \epsilon
\end{aligned}
$$

We may imagine that we have obtained this action by integrating out the short wavelength modes. In general all types of interaction are present. Clearly $\phi$ has been renormalized to give the canonical form to the kinetic term. Alternatively, we can accept that $S(\phi)$ has been generated from the Ising model by the transformation described in the previous section. We note for interest that the Ising model is identical to $\phi^{4}$ field theory in the limit $m^{2} \rightarrow-\infty, g \rightarrow \infty$ such that $6\left|m^{2}\right| / g=1$.
Suppose that we have integrated over all momemta $p>\Lambda$ and that the effective parameters are $m^{2}(\Lambda, T)$ and $g(\Lambda, T)$. We shall also allow for multiplicative field renormalization constant $Z(\Lambda, T)$. Now integrate over the next momentum slice. Write

$$
\phi(\mathbf{x})=\phi_{>}(\mathbf{x})+\phi_{<}(\mathbf{x}) .
$$

$\phi_{>}$contains contributions from momenta in the range $\Lambda-\delta \Lambda \leq p<\Lambda$.
$\phi_{<}$contains contributions from momenta in the range $0 \leq p<\Lambda-\delta \Lambda$.

Then

$$
\mathcal{Z}=\int d \phi_{<} d \phi_{>} e^{-S\left(\phi_{>}+\phi_{<}\right)}
$$

We do the integrals over $\phi_{>}$to get an action as a function of $\phi_{<}$only.

$$
\begin{aligned}
S\left(\phi_{<}+\phi_{>}\right)=S\left(\phi_{<}\right)+S\left(\phi_{>}\right) & +\int d \mathbf{x}\left[\nabla \phi_{>} \nabla \phi_{<}+m^{2} \phi_{<} \phi_{>}\right] \\
& +\frac{g}{12} \int d \mathbf{x}\left[2 \phi_{<}^{3} \phi_{>}+3 \phi_{<}^{2} \phi_{>}^{2}+2 \phi_{<} \phi_{>}^{3}\right] .
\end{aligned}
$$

The term quadratic in the fields vanishes identically. Since in $p$-space $\phi_{>}$and $\phi_{<}$ have disjoint support

$$
\int d \mathbf{x} \phi_{>}(\mathbf{x}) \phi_{<}(\mathbf{x})=\int d \mathbf{p} \tilde{\phi}_{<}(\mathbf{p}) \tilde{\phi}_{>}(\mathbf{p})=0
$$

Then

$$
\mathcal{Z}=\int d \phi_{<} e^{-S\left(\phi_{<}\right)} \int d \phi_{>} e^{-S\left(\phi_{>}\right)} e^{-\frac{g}{12} \int d \mathbf{x}\left[2 \phi_{<}^{3} \phi_{>}+3 \phi_{<}^{2} \phi_{>}^{2}+2 \phi_{<} \phi_{\lambda}^{3}\right]} .
$$

As before we expand all exponentials of non-quadratic terms
$\mathcal{Z}=$

$$
\begin{aligned}
& \int d \phi_{<} e^{-S\left(\phi_{<}\right)} \int d \phi_{>} e^{-\frac{1}{2}\left(\nabla \phi_{>}^{2}+\frac{1}{2} m^{2} \phi_{>}^{2}\right)} \cdot\left[1-\frac{g}{4!} \phi_{>}^{4}+\ldots\right] . \\
& {\left[1-\frac{g}{12}\left(2 \phi_{<}^{3} \phi_{>}+3 \phi_{<}^{2} \phi_{>}^{2}+2 \phi_{<} \phi_{>}^{3}\right)+\frac{g^{2}}{288}\left(2 \phi_{<}^{3} \phi_{>}+3 \phi_{<}^{2} \phi_{>}^{2}+2 \phi_{<} \phi_{>}^{3}\right)^{2}-\ldots\right] .}
\end{aligned}
$$

The integrals over odd functions of $\phi_{<}$vanish and so will be omitted from now on.
After the $d \phi_{>}$integrals have been done we are left with a polynomial in $\phi_{<}$ and its derivatives. We gather these terms up and absorb them into $S\left(\phi_{<}\right)$by a redefinition or renormalization of the coupling constants.

The important one-loop terms and their diagrammatic representation are
$-\frac{g}{4} \int d \mathbf{x} \phi_{>}^{2} \phi_{<}^{2}$
$\ldots$ is the propagator of $\phi_{>}$and has support in $p$-space only for $\Lambda-\delta \Lambda \leq p<\Lambda$. The last of the terms above is zero since $\phi_{<}$has disjoint $p$-space support from that of the intermediate propagator.
We can now read off the renormalizations of $m^{2}(\Lambda, T)$ and $g(\Lambda, T)$ to 1-loop

$$
m^{2}(\Lambda-\delta \Lambda, T)=m^{2}(\Lambda, T)+\frac{g(\Lambda, T)}{2} \int_{\Lambda-\delta \Lambda}^{\Lambda} \frac{d^{D} p}{(2 \pi)^{D}} \frac{1}{\mathbf{p}^{2}+m^{2}(\Lambda, T)}
$$

In momentum space we have for the 4 -point function

$$
\frac{g^{2}}{16} \int \frac{d^{D} q}{(2 \pi)^{D}} \tilde{\phi}_{<}^{2}(\mathbf{q}) \Gamma(\mathbf{q}) \tilde{\phi}_{<}^{2}(-\mathbf{q})
$$

where

$$
\Gamma(\mathbf{q})=\int_{\Lambda-\delta \Lambda}^{\Lambda} \frac{d^{D} p}{(2 \pi)^{D}} \frac{1}{\mathbf{p}^{2}+m^{2}(\Lambda, T)} \frac{1}{(\mathbf{p}+\mathbf{q})^{2}+m^{2}(\Lambda, T)}
$$

with the restriction $\Lambda-\delta \Lambda \leq|\mathbf{p}+\mathbf{q}|<\Lambda$.
We can expand $\Gamma(\mathbf{q})=\Gamma(0)+q^{2} \Gamma^{\prime}(0)+\ldots$ and then the operator generated is

$$
\frac{g^{2}}{16}\left[\Gamma(0) \int d \mathbf{x} \phi_{<}^{4}+4 \Gamma^{\prime}(0) \int d \mathbf{x}\left(\phi_{<} \nabla \phi_{<}\right)^{2}+\ldots\right]
$$

Note that new operators are generated as well as ones we are interested in. It should be remarked at this point that the analysis of the higher dimension operators generated in this way is not easy and is better approached by other renormalisation group techniques which will be touched upon later. However, there does exist work that has pushed the above style of analysis, i.e., momentum thinning, successfully to the study of the role of such operators. To 1-loop we do not encounter these difficulties. Also note that because the graph

is independent of $\mathbf{q}$ we do not generate the operator $\left(\nabla \phi_{<}\right)^{2}$ to 1-loop. More on this later.
Then we find the equation for $g$

$$
g(\Lambda-\delta \Lambda, T)=g(\Lambda, T)-\frac{3}{2} g^{2}(\Lambda, T) \int_{\Lambda-\delta \Lambda}^{\Lambda} \frac{d^{D} p}{(2 \pi)^{D}} \frac{1}{\left(\mathbf{p}^{2}+m^{2}(\Lambda, T)\right)^{2}} .
$$

We note that from the equation for $m^{2}$ the renormalization is positive. Hence if we want

$$
\lim _{\Lambda \rightarrow 0} m^{2}\left(\Lambda, T_{c}\right)=0
$$

we require $m^{2}(\Lambda, T)<0$ : the "bare" mass is negative. The expansion is still fine since it is only necessary that the gaussian exponent gives convergent integrals. This demands only that

$$
\Lambda^{2}>-m^{2}(\Lambda, T) \quad \forall \Lambda
$$

It can be verified in what follows that this inequality is always respected.
We now rewrite the two renormalization equations in differential form in terms of dimensionless quantities.

$$
\begin{aligned}
u^{2}(b, T) & =\Lambda^{-2} m^{2}(\Lambda, T) \\
\lambda(b, T) & =\Lambda^{-\epsilon} g(\Lambda, T)
\end{aligned}
$$

where $b=\log \left(\Lambda_{0} / \Lambda\right)$ and $\epsilon=4-D . \Lambda_{0}$ is the cut-off for the original theory. Then we have the evolution equations

$$
\begin{aligned}
\frac{d u^{2}}{d b} & =2 u^{2}+\frac{\Omega_{D}}{2(2 \pi)^{D}} \frac{\lambda}{1+u^{2}} \\
\frac{d \lambda}{d b} & =\epsilon \lambda-\frac{3 \Omega_{D}}{2(2 \pi)^{D}} \frac{\lambda^{2}}{\left(1+u^{2}\right)^{2}}
\end{aligned}
$$

$\Omega_{D}$ is the surface area of a unit sphere in $D$ dimensions: $\Omega_{4}=2 \pi^{2}$.
In order to integrate these equations the propagator for $\phi_{<}$must take the canonical form $1 /\left(\mathbf{p}^{2}+m^{2}\right)$. In general, the renormalized action, $S_{R}\left(\phi_{<}\right)$will be of the form

$$
\begin{aligned}
S_{R}\left(\phi_{<}\right) & =S\left(\phi_{<}\right)+\frac{1}{2} \delta m^{2} \phi_{<}^{2}+\frac{1}{4!} \delta g \phi_{<}^{4} \\
& -\frac{1}{2} \delta(\log Z)\left(\nabla \phi_{<}\right)^{2}+\frac{1}{4!} \delta g^{\prime}\left(\phi_{<} \nabla \phi_{<}\right)^{2}+\ldots
\end{aligned}
$$

Thus we must rescale the field to give the canonical quadratic part. Thus the new field for the next iteration of the procedure is

$$
\phi(\mathbf{x})=\left(1-\frac{1}{2} \frac{d \log Z}{d b} \delta b\right) \phi_{<}(\mathbf{x}) .
$$

This defines the renormalized field $\phi$ for finite $b$

$$
\phi(\mathbf{x}, b)=Z^{-\frac{1}{2}}(b, T) \phi(\mathbf{x}, 0) .
$$

Now we have additional renormalizations of $u^{2}$ and $\lambda$

$$
u_{R}^{2}(b, T)=Z(b, T) u^{2}(b, T) \quad \lambda_{R}(b, T)=Z^{2}(b, T) \lambda(b, T)
$$

and then it follows that

$$
\begin{aligned}
\frac{d u_{R}^{2}}{d b} & =\frac{d(\log Z)}{d b} u_{R}^{2}+Z^{-1}\left(\frac{d u^{2}}{d b}\right)_{Z=1} \\
\frac{d \lambda_{R}}{d b} & =2 \frac{d(\log Z)}{d b} \lambda_{R}+Z^{-2}\left(\frac{d \lambda}{d b}\right)_{Z=1}
\end{aligned}
$$

However, we have noted that to the order in which we are working,(1-loop), $Z=1$. Since we shall be expanding in $\epsilon$ this means that $Z=1$ to $O(\epsilon)$ and so $d(\log Z) / d b \sim O\left(\epsilon^{2}\right)$. Henceforth, we set $Z=1$ above, and identify $\left(u_{R}, \lambda_{R}\right)$ with $(u, \lambda)$.
It is important to remark at this stage that the renormalization choices I am making (e.g. defining the coefficient of the kinetic term to be unity), are not forced on me by physics: they are convenient for the perturbative-style analysis. Other choices may be necessary in more complex situations in order to reveal the structure of more complex phase transitions in the most effective way.
The transformation takes the form

$$
S\left(\phi, m^{2}, g_{n}, \Lambda_{0}\right) \begin{array}{cl}
\text { integration } \\
& \text { field } \xrightarrow{\text { renorm. }}
\end{array} \quad S\left(Z^{-\frac{1}{2}} \phi, m^{2}(b), g_{n}(b), e^{-b} \Lambda_{0}\right) .
$$

Here $Z \equiv Z(b)$ and $g_{n}$ is the coupling associated with field monomial of order $n$. This forms the major part of the renormalization group transformation to be discussed later. The derived equations are a form of the renormalization group flow equations for $\left(u^{2}, \lambda\right)$. Note that by dealing with dimensionless quantities all explicit reference to the cut-off $\Lambda$ disappears.

Consider a flow equation of the form

$$
\frac{d \lambda}{d b}=\beta(\lambda)
$$

This equation has fixed points $\lambda_{p}^{*}$ where $\beta\left(\lambda_{p}^{*}\right)=0$, e.g.,

Fixed points $\lambda_{p}^{*}$ where $\beta^{\prime}\left(\lambda_{p}^{*}\right)<0$ are Infra-Red attractive, and alternatively if $\beta^{\prime}\left(\lambda_{p}^{*}\right)>0$ the points are Ultra-Violet attractive.
Note that
(1) In statistical mechanics we are given the UV or bare coupling $\lambda(0, T)$, and the IR or renormalized coupling is an IR point of $\beta(\lambda)$.
(2) In quantum field theory we are given the IR or renormalized coupling $\lambda(\infty, T)$ : it is a renormalization condition from experiment or other low energy condition. Since $\lambda(\infty, T)$ is not generally a fixed point of $\beta(\lambda)$ it must be that the UV or bare coupling is a UV fixed point of $\beta$. (It should be noted that although we have worked exclusively in Euclidean space it is believed that the divergences are the same as for the Minkowski version of the theory. This belief can be demonstated in perturbation theory.)
In our calculation we find the fixed points $\left(u^{* 2}, \lambda^{*}\right)$

$$
\left.\begin{array}{lcl}
\epsilon<0 & (0 & , 0) \\
\text { trivial f.p. - IR attractive } \\
\epsilon>0 & (0 & , 0)
\end{array} \begin{array}{l}
\text { trivial f.p. - UV attractive } \\
\\
\\
\\
\left(-\frac{\epsilon}{6}\right.
\end{array}, \frac{16 \pi^{2}}{3} \epsilon\right) \quad \text { non-trivial f.p. - IR attractive }
$$

It is believed that there are no others, not even at $\lambda=\infty$. This means for quantum field theory that there is no UV fixed point to be associated with the bare coupling except the one at $(0,0)$ when $\epsilon<0$. Hence, it follow that

$$
\begin{array}{ll}
\epsilon<0 & \lambda_{R}=0 \\
\epsilon \geq 0 & \lambda_{R} \leq \frac{16 \pi^{2}}{3} \epsilon,
\end{array}
$$

where $\lambda^{R}=\lambda(\infty, T)$. This is the statement of triviality for $\phi^{4}$ quantum field theory. It means that in dimension four or greater the only consistent renormalized $\phi^{4}$ theory in the limit of infinite cut-off is a free theory: $\lambda_{R}=0$. Of course, we are not required to take the cut-off to infinity, rather we should keep it much larger than the physical momentum scales on which the theory is being applied. Even then, for finite $\Lambda$ the analysis presented gives an upper limit to $\lambda_{R}$. Such upper limits have been used to set upper bounds on the Higgs mass in the most common version of the standard model.

Since $\epsilon$ is small we can get a reliable expansion in $\epsilon$ for both $u^{* 2}$ and $\lambda^{*}$. This is the epsilon expansion

$$
\lambda^{*}=\sum_{n=1}^{\infty} a_{n} \epsilon^{n} .
$$

It is hoped that the radius of convergence is greater than one, thus including results for $D=3$.
Write the equation for $u^{2}$ as

$$
\frac{d u^{2}}{d b}=f\left(u^{2}\right)
$$

We now show how to derive the postulated scaling behaviour from the flow equations.
For $\Lambda \xi \ll 1$ all parameters have reached their low-energy renormalized values. Let

$$
A=\frac{1}{\Lambda \xi} \gg 1 \Rightarrow b=\log \left(A \xi \Lambda_{0}\right)
$$

We have

$$
u(b, T)=\frac{m(b, T)}{\Lambda}=\frac{1}{\Lambda \xi}=A
$$

This follows since for $A \gg 1, m(b, T)=\xi^{-1}$. Then

$$
\begin{aligned}
\int_{u^{2}(\bar{b}, T)}^{A^{2}} \frac{d u^{2}}{f\left(u^{2}\right)} & =b-\bar{b} \\
& =\log (A \xi \bar{\Lambda}) \\
& =\log (\xi)+C
\end{aligned}
$$

with $\bar{\Lambda}=e^{-\bar{b}} \Lambda_{0}$ and $\xi^{-1} \ll \bar{\Lambda} \ll \Lambda_{0}$, but such that

$$
\lambda(\bar{b}, T) \approx \lambda^{*}
$$

This will always be possible if $\xi$ is big enough. The key point is that we consider the flow first from $\Lambda_{0}$ to $\bar{\Lambda}$ so that $\lambda$ flows very close to its IR attractive fixed point. We still have the condition that $\bar{\Lambda} \gg \xi$. We then consider the flow to $\Lambda \ll \xi^{-1}$. For this part of the flow $\lambda$ is fixed at its fixed point value $\lambda^{*}$. It is from this latter part of the flow that the scaling form for $\xi$ as a function of $t$ follows. The sequence of flows can be summarized thus

$$
\begin{array}{cccccc}
\Lambda_{0} & \gg & \bar{\Lambda} & \gg \xi^{-1} & \gg \\
\lambda(0, T) & & \lambda(\bar{b}, T) \approx \lambda^{*} & & & \lambda(\bar{b}, T) \approx \lambda^{*} \\
m^{2}(0, T) & & m^{2}(\bar{b}, T) & & & m^{2}(b, T)=\xi^{-2} \\
0 & \rightarrow & \bar{b} & & \rightarrow & b
\end{array}
$$

Mow, for $T=T_{c}, \quad \xi=\infty$. Hence it follow from above that

$$
\int_{u^{2}\left(\bar{b}, T_{c}\right)}^{A^{2}} \frac{d u^{2}}{f\left(u^{2}\right)}=\infty
$$

Thus $u\left(\bar{b}, T_{c}\right)=u^{*}$ and the integral has a logarithmic singularity. We write

$$
u^{2}\left(\bar{b}, T_{c}\right)=u^{* 2}+B t, \quad t=\frac{T-T_{c}}{T_{c}}
$$

Then

$$
\begin{aligned}
\int_{u^{* 2}+B t}^{A^{2}} \frac{d u^{2}}{f\left(u^{2}\right)} & =\log \xi(t)+C \Rightarrow \\
\frac{d \xi(t)}{\xi(t)} & =\frac{B d t}{f\left(u^{* 2}+B t\right)} \\
& =-\frac{1}{f^{\prime}\left(u^{* 2}\right)} \frac{d t}{t}
\end{aligned}
$$

From above we have that

$$
f^{\prime}\left(u^{* 2}\right)=\left(\frac{\partial f}{\partial u^{2}}\right)_{\left(u^{* 2}, \lambda^{*}\right)}=2-\frac{1}{3} \epsilon .
$$

Hence we obtain the prediction that

$$
\xi(t)=D t^{-\nu} \quad \text { with } \quad \nu=\frac{1}{2}+\frac{1}{12} \epsilon .
$$

The solution of the full flow equations looks like

We remark the following points
(1) In a general description, the theory for some intermediate cut-off will be given by the values of a complete set of coupling constants associated with all possible field monomials in the action. These couplings, denoted $h_{i}$, will be functions of $\Lambda$ and $T$, and they flow in such a way that the low-energy predictions of the theory are independent of $\Lambda$. We would expect the flow equations to take the form

$$
\frac{d h_{i}}{d b}=\beta_{i}(\mathbf{h})
$$

The diagram of the flow is then, in principle, an $\infty$-dimensional space.
(2) The critical surface is the manifold of all theories in coupling constant space, $\mathbf{h}$, which flow to a fixed point. If there is more than one fixed point then the critical surface is divided into domains of attraction each associated with one fixed point. All theories in the critical surface have $\xi=\infty$, i.e., they are at a continuous transition. This follows because it requires $b \rightarrow \infty$ to flow to $u^{2}=A^{2}$ which is the reference theory. Hence for all finite $b$ we must have $\Lambda \equiv b \Lambda_{0}>\xi^{-1}$ which implies that $\xi=\infty$.
(3) As $T$ changes the theory follows a trajectory (dotted line) which intersects the critical surface at $T=T_{c}$. As shown above the critical exponents are given by the behaviour of trajectories in the neighbourhood of the IR fixed point. Hence we only need to calculate $\beta_{i}(\mathbf{h})$ in this neighbourhood.
(4) The number of parameters we need to tune in order to intercept the critical surface is clearly equal to the number of unstable directions at the fixed point. In our calculation the number of such unstable parameters is one, namely the temperature $T$ (i.e., $u^{2}(\bar{b}, T)$ which is controlled by $T$ ). Thus the transition corresponds to an ordinary critical point.
A fixed point with two unstable directions requires two external varibles to be tuned e.g., $T, P$, and thus corresponds to a tricritical or bicritical point.
(5) The critical surface sparates the two phases i.e., the symmetric phase from the broken phase.
(6) We expand $\beta_{i}(\mathbf{h})$ about the fixed point, $\mathbf{h}^{*}$. This linearizes the flow equations. Writing $\Delta_{i}=h_{i}-h_{i}^{*}$

$$
\frac{d \Delta_{i}}{d b}=R_{i j} \Delta_{i}+O\left(\Delta^{2}\right)
$$

The eigenvectors, $\mathbf{e}_{p}$, of $R_{i j}$ define the flow directions and the associated eigenvalues, $\mu_{p}$ determine the stability properties

$$
\mu_{p}<0 \text { stable, } \mu_{p}>0 \text { unstable, } \mu_{p}=0 \text { tricky . }
$$

(7) For operator $g_{n} \phi^{2 n}$ we have $\left[g_{n}\right] \equiv d_{n}=n(D-2)-D$. Then $\beta_{n}(\mathbf{h})$ has the linear term

$$
\beta_{n}(\mathbf{h})=-d_{n} h_{n}+\ldots
$$

(The $h_{n}$ are the dimensionless versions of the $g_{n}$.) This coupling will be stable for $d_{n}>0$ unless there are any very large renormalizations from other terms. Although large corrections cannot be ruled out it is expected that since, in practical cases, the $d_{n}$ are integers we find that the operators are stable if

$$
n>\frac{D}{D-2} .
$$

Such operators are said to be irrelevant since their couplings automatically flow onto the critical surface and do not need to be "tuned".

$$
\begin{array}{ccccl}
D=4 & n>2 & \Rightarrow & \phi^{6}, \phi^{8}, \ldots & \text { irrelevant } \\
D=3 & n>3 & \Rightarrow & \phi^{8}, \ldots & \text { irrelevant }
\end{array}
$$

This reflects the result of our earlier perturbative calculation of $D_{c}$ and the criteria for the validity of Landau theory.
(7) The flow equations are a coupled non-linear set. The $h_{n}$ of different field monomials get mixed. This reflects the operator mixing induced by renormalization. In the linearized version the eigenvalues of $R_{i j}$ define eigenoperators: linear combinations of field monomials which do not mix with each other. This can be generalized to the full non-linear version of the flow equations.
(8) In the Landau theory we associate the coefficient of $M^{4}$ with the lowmomentum dimensionful coupling

$$
g(T)=\Lambda_{0}^{\epsilon} \lim _{b \rightarrow \infty} e^{-\epsilon b} \lambda(b, T) .
$$

This is because $g(T)$ is the coefficient of $M^{4}$ in the effective action derived by the Legendre transform. ( $Z=1$ to $O(\epsilon)$ otherwise we would need to include $Z^{2}$ in the definition of $\left.g(T)\right)$.
Let

$$
g(b, T)=e^{-\epsilon b} \lambda(b, T)
$$

Then the equation for the flow of $\lambda$ in the neighbourhood of the fixed point implies

$$
\frac{d g}{d b}=-\frac{3}{16 \pi^{2}} e^{\epsilon b} g^{2}
$$

or

$$
\frac{1}{g(\bar{b})}-\frac{1}{g(b)}=-\frac{3}{16 \pi^{2}} e^{\bar{\epsilon} \bar{b}}\left(e^{\epsilon(b-\bar{b})}-1\right)
$$

and thus

$$
\begin{aligned}
& g(b)=\frac{g(\bar{b})}{1+\frac{a(\epsilon)}{\epsilon}\left(e^{\epsilon(b-\bar{b})}-1\right)} . \\
& a(\epsilon)=\frac{3}{16 \pi^{2}} e^{e \bar{b}} .
\end{aligned}
$$

Denoting $g(T) \equiv g(\infty, T)$ we have the following results
$\epsilon>0: g(T)=0$. Hence Landau's method fails and the relevant physics is encoded in how $g(b, T) \rightarrow 0$ as $b \rightarrow \infty$.
$\epsilon<0$ : We have

$$
g(T)=\frac{g(\bar{b})}{1+\frac{a(\epsilon)}{|\epsilon|}} .
$$

Since here $g(T)$ is finite and non-zero Landau's method works. As before we are assuming that $\bar{b}$ is large enough so that the equations we integrated to get this result are valid. In this case $g(T)$ is actually independent of $\bar{b}$.
$\epsilon=0: g(T)=0$. Landau theory fails but

$$
\begin{aligned}
& g(b)=\frac{g(\bar{b})}{1+\frac{3}{16 \pi^{2}}(b-\bar{b})} \\
& g(b)=\frac{g(\bar{b})}{1+\frac{3}{16 \pi^{2}} \log \frac{\bar{\Lambda}}{\Lambda}} .
\end{aligned}
$$

I.e., only logarithmic violations of Landau theory.

### 4.5 The Renormalization Group in General

Our procedure so far consists of "thinning" the degrees of freedom by integrating out the high momentum modes. We can define the transformation $(\lambda<1)$

$$
S(\lambda) H(\phi)=H(\lambda, \phi, \lambda \Lambda)
$$

with $H(\phi) \equiv H(1, \phi, \Lambda)$ as the bare or microscopic Hamiltonian. The explicit $\lambda$ dependence is there because the couplings have changed in a $\lambda$-dependent way. The $S(\lambda)$ form a semi-group

$$
S\left(\lambda_{1}\right) S\left(\lambda_{2}\right)=S\left(\lambda_{1} \lambda_{2}\right)
$$

There is no inverse because of the existence of fixed points: information lost cannot be retrieved.
It is convenient to perform a rescaling at this stage

$$
\begin{array}{cl}
\mathbf{x} \rightarrow \mathbf{x}^{\prime}=\lambda \mathbf{x} & \\
\mathbf{q} \rightarrow \mathbf{q}^{\prime}=\lambda^{-1} \mathbf{q} & \\
\phi \rightarrow \phi^{\prime} & \phi^{\prime}\left(\mathbf{q}^{\prime}\right)=A^{-\frac{1}{2}}(\lambda) \phi(\mathbf{q}) \\
\lambda \Lambda \rightarrow \Lambda & \text { momentum rescaling } \\
\lambda \Lambda \text { field rescaling } \\
& \text { cut-off rescaling }
\end{array}
$$

The cut-off is rescaled back to its original value. The new fields $\phi^{\prime}$ have support $0 \leq \mathbf{q}^{\prime} \leq \Lambda$ in momentum space, i.e., the same support as the original fields before thinning. $A(\lambda)$ is chosen by convenience. It may be chosen so that the coefficient of $\frac{1}{2}(\nabla \phi)^{2}$ in the new Hamiltonian is one, but other choices can turn out to be more appropriate in more complex theories.
We then define the renormalized Hamiltonian $H_{R}(\phi, \Lambda)$ by

$$
\mathcal{H}_{R}\left(\phi^{\prime}, \Lambda\right)=H(\lambda, \phi, \lambda \Lambda) .
$$

For example consider the kinetic term in $H$

$$
Z^{-1}(\lambda) \int_{0}^{\lambda \Lambda} \frac{d^{D} q}{(2 \pi)^{D}} \mathbf{q}^{2}|\tilde{\phi}(\mathbf{q})|^{2}
$$

Change variables to $\mathbf{q}^{\prime}=\lambda^{-1} \mathbf{q}$

$$
\begin{aligned}
& =Z^{-1}(\lambda) \lambda^{D+2} \int_{0}^{\Lambda} \frac{d^{D} q^{\prime}}{(2 \pi)^{D}} \mathbf{q}^{\prime 2}|\tilde{\phi}(\mathbf{q})|^{2} \\
& =Z^{-1}(\lambda) \lambda^{D+2} \int_{0}^{\Lambda} \frac{d^{D} q{ }^{\prime}}{(2 \pi)^{D}} \mathbf{q}^{\prime 2} A(\lambda)\left|\tilde{\phi}^{\prime}\left(\mathbf{q}^{\prime}\right)\right|^{2} \\
& =A(\lambda) Z^{-1}(\lambda) \lambda^{D+2} \int_{0}^{\Lambda} \frac{d^{D} q}{(2 \pi)^{D}} \mathbf{q}^{2}\left|\tilde{\phi}^{\prime}(\mathbf{q})\right|^{2}
\end{aligned}
$$

If we choose $A(\lambda)=Z(\lambda) \lambda^{-(D+2)}$, then the kinetic term in $H_{R}(\phi, \Lambda)$ has the canonical form.

The renormalization group transformation is $R(\lambda)$ where

$$
R(\lambda) H(\phi, \Lambda)=H_{R}(\phi, \Lambda)
$$

$H_{R}$ is defined on the same lattice as is $H$, but all dimensionful observables are scaled in the appropriate manner.
Define

$$
G\left(\mathbf{q}_{1}, \ldots, \mathbf{q}_{n}\right)=<\phi\left(\mathbf{q}_{1}\right) \ldots \phi\left(\mathbf{q}_{n}\right)>.
$$

Then we must have

$$
\begin{array}{ccc}
<\phi\left(\mathbf{q}_{1}\right) \ldots \phi\left(\mathbf{q}_{n}\right)> & = & A^{\frac{n}{2}}(\lambda)<\phi\left(\frac{\mathbf{q}_{1}}{\lambda}\right) \ldots \phi\left(\mathbf{q}_{n}\right)>_{R} \\
\text { computed with } H & & \text { computed with } H_{R} \\
G\left(\mathbf{q}_{1}, \ldots, \mathbf{q}_{n}\right) & = & A^{\frac{n}{2}}(\lambda) G_{R}\left(\frac{\mathbf{q}_{1}}{\lambda}, \ldots, \frac{\mathbf{q}_{n}}{\lambda}\right)
\end{array}
$$

With the choice for $A(\lambda)$ above, $H_{R}$ is a function of the set of dimensionless couplings which we denote here by $\mathbf{g}(\lambda)$. then

$$
H_{R}(\phi, \Lambda)=H(\mathbf{g}(\lambda), \phi, \Lambda),
$$

and

$$
R(\lambda) H\left(\mathbf{g}_{0}, \phi, \Lambda\right)=H(\mathbf{g}(\lambda), \phi, \Lambda), \quad \mathbf{g}_{0}=\mathbf{g}(1)
$$

This defines the RG transformation on the couplings

$$
R(\lambda) \mathbf{g}_{0}=\mathbf{g}(\lambda)
$$

and since $R\left(\lambda_{1}\right) R\left(\lambda_{2}\right)=R\left(\lambda_{1} \lambda_{2}\right)$ we have

$$
R\left(\lambda_{2}\right) \mathbf{g}\left(\lambda_{1}\right)=\mathbf{g}\left(\lambda_{1} \lambda_{2}\right)
$$

Thus

$$
\begin{aligned}
R(1-\alpha) \mathbf{g}(\lambda) & =\mathbf{g}(\lambda)-\alpha \lambda \frac{d}{d \lambda} \mathbf{g}(\lambda)+\ldots \Rightarrow \\
\beta_{i}(\mathbf{g}) & =-\frac{d g_{i}(\lambda)}{d \log \lambda} \\
& =\lim _{\alpha \rightarrow 0} \frac{1}{\alpha}\left[R(1-\alpha) g_{i}(\lambda)-g_{i}(\lambda)\right]
\end{aligned}
$$

This defines the function $\beta_{i}(\mathbf{g})$.
(1) $\beta_{i}$ has no explicit dependence on $\Lambda$ if $\mathbf{g}$ is a vector of dimensionless couplings. The $g_{i}$ correspond to the dimensionful couplings scaled by $\Lambda$.
(2) $\beta_{i}$ does not depend explicitly on $\lambda$ : the only $\lambda$-dependence is through $\mathbf{g}(\lambda)$ in $H$. This follows since $R(1-\alpha)$ is independent of $\lambda$. The next step along the flow in coupling constant space cannot depend on $\lambda$ since $\lambda$ tells us how far we have already evolved, or flowed, along the trajectory. However, the next step depends only on the couplings at that point on the flow and not on the flow history. This is guaranteed by the semi-group property of the RG transformation.

Setting $b=-\log \lambda$ we have

$$
\frac{d g_{i}}{d b}=\beta_{i}(\mathbf{g})
$$

A fixed point is determined by $\beta_{i}\left(\mathbf{g}^{*}\right)=0, \forall i$. Then

$$
R(\lambda) H\left(\mathbf{g}^{*}, \phi, \Lambda\right)=H\left(\mathbf{g}^{*}, \Lambda\right)
$$

and hence from above, when $\mathbf{g}=\mathbf{g}^{*}$

$$
\begin{aligned}
G\left(\mathbf{q}_{1}, \ldots ; \mathbf{q}_{n}\right) & =A^{\frac{n}{2}}(\lambda) G\left(\frac{\mathbf{q}_{1}}{\lambda}, \ldots ; \frac{\mathbf{q}_{n}}{\lambda}\right) \\
A(\lambda) & =\lambda^{-(D+2)} Z(\lambda) .
\end{aligned}
$$

Then writing $Z(\lambda)=\lambda^{2 \eta_{\phi}}$ we have

$$
A(\lambda)=\lambda^{-2\left(D-\Delta_{\phi}\right)}, \quad \Delta_{\phi}=\left(\frac{D}{2}-1\right)+\eta_{\phi}
$$

and thus

$$
G\left(\mathbf{q}_{1}, \ldots ; \mathbf{q}_{n}\right)=\lambda^{-n\left(D-\Delta_{\phi}\right)} G\left(\frac{\mathbf{q}_{1}}{\lambda}, \ldots ; \frac{\mathbf{q}_{n}}{\lambda}\right)
$$

This is the scaling law for Green functions at the fixed point.

$$
\begin{array}{rcl}
\Delta_{\phi} & \text { is the scaling dimension of } & \phi(\mathbf{x}) \\
\left(\frac{D}{2}-1\right) & \text { is the engineering dimension of } & \phi(\mathbf{x}) \\
\eta_{\phi} & \text { is the anomalous dimension of } & \phi(\mathbf{x}) .
\end{array}
$$

The full renormalization group thus consists of two stages.
Momentum space

## Coordinate space

(1) The special form for $\phi^{\prime}$ applies at the fixed point.
(2) Since the full transformation, $R(\lambda)$, leaves $\Lambda$, or $a$ unchanged the overall effect is a rescaling of the physical parameters and observables only. $\Lambda$ plays no role in the dimensional analysis based on this rescaling.
(3) A general field combination $f(\phi(\mathbf{x}))$ generally "renormalizes" in a complicated way

$$
f(\phi) \xrightarrow{R} f^{\prime}(\phi),
$$

but for special combinations, the scaling fields, a dimension, $\Delta_{f}$, can be assigned

$$
f^{\prime}(\phi(\mathbf{x}))=\lambda^{\Delta_{f}} f\left(\phi^{\prime}\left(\mathbf{x}^{\prime}\right)\right)
$$

This is possible only near a fixed point.
$[(*)$ for information only - not directly part of course
(i) Before thinning have term in action of the form

$$
\int_{a} d^{D} x h f(\phi(\mathbf{x}))
$$

where $h$ is a coupling or external field. After thinning this term becomes

$$
\int_{a / \lambda} d^{D} x h f^{\prime}(\phi(\mathbf{x}))
$$

Near to the fixed point we can write this term alternatively as

$$
\begin{aligned}
& \int_{a / \lambda} d^{D} x h \lambda^{\Delta_{f}} f\left(\phi^{\prime}\left(\mathbf{x}^{\prime}\right)\right), \quad \mathbf{x}^{\prime}=\lambda \mathbf{x} . \\
= & \int_{a} d^{D} x^{\prime} h \lambda^{\Delta_{f}-D} f\left(\phi^{\prime}\left(\mathbf{x}^{\prime}\right)\right) .
\end{aligned}
$$

But from the RG we are told that this term in the rescaled action must be

$$
\int_{a} d^{D} x h \lambda^{-\Delta_{h}} f(\phi(\mathbf{x}))
$$

and hence we verify the existence of a scaling dimension for the operator function $f$ with dimension $\Delta_{f}$ which, comparing the last two expressions, is given by $\Delta_{f}=D-\Delta_{h}$.
(ii) An alternate way of seeing this is to use the scaling rules for Green functions near to a fixed point. These rules are derived in section 5 and you should refer back to here after reading it. We have

$$
\frac{\partial}{\partial h} G\left(\mathbf{x}_{1}, \ldots, \mathbf{x}_{n} ; h\right)=\int d^{D} y G_{f}\left(\mathbf{x}_{1}, \ldots, \mathbf{x}_{n}, y ; h\right)
$$

where $G_{f}$ means an insertion of $f(\phi)$ into the expectation value. By the association of a dimension $\Delta_{f}$ with $f$ we use the scaling rules to write this in the alternative form:

$$
=\int d^{D} y \lambda^{n \Delta_{\phi}+\Delta_{f}} G_{f}\left(\lambda \mathbf{x}_{1}, \ldots, \lambda \mathbf{x}_{n}, \lambda y ; \lambda^{-\Delta_{h}} h\right)
$$

However, this last expression must also be given by

$$
\begin{aligned}
& \frac{\partial}{\partial h}\left[\lambda^{n \Delta_{\phi}} G\left(\lambda \mathbf{x}_{1}, \ldots, \lambda \mathbf{x}_{n} ; \lambda^{-\Delta_{h}} h\right)\right] \\
= & \int d^{D} y \lambda^{n \Delta_{\phi}} \lambda^{-\Delta_{h}} G_{f}\left(\lambda \mathbf{x}_{1}, \ldots, \lambda \mathbf{x}_{n}, y ; \lambda^{-\Delta_{h}} h\right) \\
= & \lambda^{D} \int d^{D} y^{\prime} \lambda^{n \Delta_{\phi}} \lambda^{-\Delta_{h}} G_{f}\left(\lambda \mathbf{x}_{1}, \ldots, \lambda \mathbf{x}_{n}, \lambda y^{\prime} ; \lambda^{-\Delta_{h}} h\right) .
\end{aligned}
$$

Comparing these two versions we find $\Delta_{f}=\Delta-\Delta_{h}$ as before.
(4) The anomalous dimension, $\eta_{\phi}$, is computed from $Z(\lambda)$, the field renormalisation constant.

Now consider the flow in the neighbourhood of a fixed point. Write

$$
\mathrm{g}=\mathrm{g}^{*}+\mathbf{v}
$$

Then

$$
\frac{d v_{i}}{d b}=K_{i j}\left(\mathbf{g}^{*}\right) v_{j}
$$

The eigenvalues of $K_{i j}$ are $\Delta_{\alpha}$ with eigenvectors $\mathbf{e}_{a}$.
Then we find

$$
\begin{aligned}
\mathbf{v} & =\sum_{\alpha} h_{\alpha} \mathbf{e}_{\alpha} \Rightarrow \\
\frac{d h_{\alpha}}{d b} & =\Delta_{\alpha}\left(g^{*}\right) h_{\alpha} \quad \text { no sum on } \alpha, \quad \Rightarrow \\
h_{\alpha} & =h_{\alpha}^{(0)} \lambda^{-\Delta_{\alpha}} .
\end{aligned}
$$

Remember that $b=\log \lambda, \quad \lambda=\Lambda / \Lambda_{0}<1$.
If $\Delta_{\alpha}>0$ the eigencoupling $h_{\alpha}$ is unstable and is repelled by the fixed point and vice-versa if $\Delta_{\alpha}<0$. We have recovered the result that we stated before in a slightly different context namely that every fixed point corresponds to a continuous transition and can be labelled by the number $r$ of repulsive (i.e.,
positive) eigenvalues. then $r$ is the number of external fields that must be tuned so that we see the transition controlled by that fixed point.

In general the Hamiltonian is

$$
H=\int d \mathbf{x} \sum_{n} g_{n} A_{n}(\mathbf{x})=H^{*}+\int d \mathbf{x} \sum v_{n} A_{n}(\mathbf{x})
$$

where the $A_{n}$ are general operators and are functions of the fields. Near a fixed point we can write instead

$$
H=H^{*}+\int d \mathbf{x} \sum_{\alpha} h_{\alpha} A_{\alpha}(\mathbf{x}),
$$

where

$$
\begin{array}{cc}
A_{\alpha}=\sum_{n}\left(\mathbf{e}_{\alpha}\right)_{n} A_{n}(\mathbf{x}) & \text { scaling fields } \\
h_{\alpha}=\left(\mathbf{u}_{\alpha}\right)_{n} g_{n} & \text { scaling couplings. }
\end{array}
$$

Here we have defined the vectors $\mathbf{u}_{\alpha}$ by

$$
\mathbf{e}_{\alpha} \cdot \mathbf{u}_{\beta}=\delta_{\alpha \beta} \quad \Rightarrow \quad\left(\mathbf{e}_{\alpha}\right)_{n}\left(\mathbf{u}_{\alpha}\right)_{m}=\delta_{n m}
$$

Now we define $\left[A_{\alpha}\right]=\Delta_{A_{\alpha}}$ and we have that $\left[h_{\alpha}\right]=\Delta_{\alpha}$. But $H$ is dimensionless and so we must have

$$
\Delta_{A_{\alpha}}=D-\Delta_{\alpha} .
$$

$\Delta_{\alpha}$ is an eigenvalue of the linearized RG transformation.
Denote Green functions by

$$
G\left(\mathbf{x}_{1}, \ldots, \mathbf{x}_{n} ; \mathbf{h}\right)=<\phi\left(\mathbf{x}_{1} \ldots \phi\left(\mathbf{x}_{n}\right)>_{c}\right.
$$

where $\mathbf{h}$ is the vector of eigencouplings. Near a fixed point we have

$$
G\left(\mathbf{x}_{1}, \ldots, \mathbf{x}_{n} ; \mathbf{h}\right)=\bar{A}^{\frac{n}{2}}(\lambda) G\left(\lambda \mathbf{x}_{1}, \ldots, \lambda \mathbf{x}_{n} ; \lambda^{-\Delta_{\alpha}} \mathbf{h}\right)
$$

where $\bar{A}^{\frac{1}{2}}=\lambda^{D} A^{\frac{1}{2}}$. The extra factor of $\lambda^{D}$ occurs when $G$ is fourier transformed from momentum space to coordinate space. But we have

$$
\bar{A}^{\frac{1}{2}}=\lambda^{D} A^{\frac{1}{2}}=\lambda^{\Delta_{\phi}},
$$

and hence it follows that

$$
G\left(\mathbf{x}_{1}, \ldots, \mathbf{x}_{n} ; \mathbf{h}\right)=(\lambda)^{n \Delta_{\phi}} G\left(\lambda \mathbf{x}_{1}, \ldots, \lambda \mathbf{x}_{n} ; \lambda^{-\Delta_{\alpha}} \mathbf{h}\right)
$$

This is the full scaling result for Green functions evaluated near to a fixed point. In the next section we shall derive the scaling theory which demonstates that such results can be obtained even when the bare theory is not near to a fixed point as long as it is sufficiently close to a critical surface, i.e., near a continuous phase transition.

Note for example that the "magnetic field", $h$, has dimension

$$
\Delta_{h}=D-\Delta_{\phi},
$$

since the relevant term in the Hamiltonian is $-\int d \mathbf{x} h \phi$ which must be dimensionless.
If $A_{\alpha}$ is a relevant operator then we must have

$$
\Delta_{h_{\alpha}}=D-\Delta_{A_{\alpha}}>0 \quad \Rightarrow \quad \Delta_{A_{\alpha}}<D
$$

So, for example, $\phi$ is a relevant operator.
We can see an immediate aplication of these ideas as follows. Let $B(\mathbf{x})$ have dimension $\Delta_{B}$ which does not necessarily satisfy $\Delta_{B}<D$, i.e., $B$ need not be a relevant operator. Let $A$ be a relevant operator conjugate to external field $h: \Delta_{A}=D-\Delta_{h}$ and $\Delta_{A}<D$. All other parameters except $h$ are fixed at their critical values, and so as $h \rightarrow 0 \quad \xi$ diverges. The corresponding generalized susceptibility is

$$
\frac{\partial^{n} \chi}{\partial h^{n}}=\int \prod d \mathbf{x}_{i}<B(0) A\left(\mathbf{x}_{1}\right) \ldots A\left(\mathbf{x}_{n}\right)>_{h} .
$$

[This follows since interesting term in $H$ is $-h \int d \mathbf{x} A(\mathbf{x})$ and we have

$$
<B(0)>=\int d \phi e^{-H} B(\phi(0)) .
$$

]
The only length scale in the problem is $\xi$ and hence on dimensional grounds

$$
\frac{\partial^{n} \chi}{\partial h^{n}} \sim \xi^{\left(n D-\Delta_{B}-n \Delta_{A}\right)}
$$

and for $n$ large enough this will diverge as $h \rightarrow 0, \quad \xi \rightarrow \infty$ if

$$
n\left(D-\Delta_{A}\right)>\Delta_{B}
$$

This will occur for some $n$ since $A$ is relevant and hence $\Delta_{A}<D$.
Thus singular thermodynamic quantities are associated with relevant operators and consequently with the unstable or repulsive eigenvalues of the linearized RG transformation.

## 5 Scaling theory

Consider the Green function for a field $\phi(\mathbf{x})$ which has dimension $\Delta_{\phi}$

$$
G\left(\mathbf{x}_{1}, \ldots, \mathbf{x}_{n} ; \mathbf{g} \mid \xi\right)=<\phi\left(\mathbf{x}_{1}\right) \ldots \phi\left(\mathbf{x}_{n}\right)>_{c} .
$$

$G$ has been labelled by $\xi$ which will be assumed to be large. $\xi$ is a dynamical variable determined by $\mathbf{g}$, the couplings in dimensionless form. From the RG we have, in general

$$
G\left(\mathbf{x}_{1}, \ldots, \mathbf{x}_{n} ; \mathbf{g} \mid \xi\right)=\bar{A}^{\frac{n}{2}}(\lambda) G\left(\lambda \mathbf{x}_{1}, \ldots, \lambda \mathbf{x}_{n} ; \mathbf{g}(\lambda) \mid \lambda \xi\right)
$$

Now consider a particular value, $\bar{\lambda}$, of $\lambda$ such that for cases where $\xi \gg 1$

$$
\bar{\lambda} \ll 1 \quad \text { and } \quad \bar{\lambda} \xi \gg 1 \quad \text { and } \quad \mathbf{g}(\bar{\lambda})=\mathbf{g}^{*} .
$$

This will always be possible if $\xi$ is large enough, although how large it must be for this to be true is a question we have not addressed. Then we can define the function $F$ by

$$
G\left(\mathbf{x}_{1}, \ldots, \mathbf{x}_{n} ; \mathbf{g} \mid \xi\right)=F\left(\mathbf{x}_{1}, \ldots, \mathbf{x}_{n} \mid \xi\right)
$$

Which, from above, means that

$$
F\left(\mathbf{x}_{1}, \ldots, \mathbf{x}_{n} \mid \xi\right)=\bar{A}^{\frac{n}{2}}(\bar{\lambda}) G\left(\bar{\lambda} \mathbf{x}_{1}, \ldots, \bar{\lambda} \mathbf{x}_{n} ; \mathbf{g}^{*} \mid \bar{\lambda} \xi\right)
$$

Then a further renormalization gives

$$
\begin{aligned}
F\left(\mathbf{x}_{1}, \ldots, \mathbf{x}_{n} \mid \xi\right) & =\bar{A}^{\frac{n}{2}}(\lambda) F\left(\lambda \mathbf{x}_{1}, \ldots, \lambda \mathbf{x}_{n} \mid \lambda \xi\right) \\
& =\lambda^{n \Delta_{\phi}} F\left(\lambda \mathbf{x}_{1}, \ldots, \lambda \mathbf{x}_{n} \mid \lambda \xi\right)
\end{aligned}
$$

The last result follows since this further renormalzation is applied to a theory near the fixed point (i.e. only the mass, $m=\xi^{-1}$, is not at its critical value) and so $\bar{A}$ takes the power-law form dictated by the linearized RG flow equations.
Thus for $\lambda \xi=p, \quad p \gg 1$ and fixed we have

$$
G\left(\mathbf{x}_{1}, \ldots, \mathbf{x}_{n} ; \mathbf{g} \mid \xi\right)=\xi^{-n \Delta_{\phi}} E\left(\xi_{1}, \ldots, \xi_{n}\right)
$$

where $\xi_{i}=\mathbf{x}_{i} / \xi$ and

$$
\begin{aligned}
E\left(\xi_{1}, \ldots, \xi_{n}\right) & =p^{n \Delta_{\phi}} F\left(p \xi_{1}, \ldots, p \xi_{n} \mid p\right) \\
& =p^{n \Delta_{\phi}} \bar{A}^{\frac{n}{2}}(\bar{\lambda}) G\left(\bar{\lambda} \mathbf{x}_{1}, \ldots, \bar{\lambda} \mathbf{x}_{n} ; \mathbf{g}^{*} \mid \bar{\lambda} p\right) .
\end{aligned}
$$

This result is a verification of the scaling hypothesis. As can be seen, all results are ultimately expressed in terms of a theory with correlation length $\bar{\lambda} p$. In order that this theory lies in that neighbourhood of the fixed point in which the linearized RG equations apply we must have that $\bar{\lambda} p$ is sufficiently large. A diagram of the flow is shown below.

What matters is that the theory with correlation length $\bar{\lambda} p$ can be so chosen to lie in the region where the linear RG approximation is good. This region is a neighbourhood of the fixed point and as long as the flow line emanating from the bare theory passes through this region then the above analysis can be applied and
the scaling behaviour derived is valid. Clearly, the range of values of temperature $T$ (near $T_{c}$ ) for which this happens depends on how close the intersection of the trajectory of bare theories with the critical surface is to $\mathbf{g}^{*}$ : if it is close to $\mathbf{g}^{*}$ then the scaling behaviour will be apparent over quite a wide range of temperatures near $T_{c}$, but the range will narrow as the distance of the intersection from $\mathbf{g}^{*}$ increases. This range of tempeatures in which the scaling behaviour is observed and the critical exponents can be measured is caled the critical region.

Now follows a few interesting consequences of scaling theory. Consider the generalized susceptibility

$$
\Gamma_{n}=\int d \mathbf{x}_{1} \ldots d \mathbf{x}_{n-1} G\left(0, \mathbf{x}_{1}, \ldots, \mathbf{x}_{n-1} ; \mathbf{g} \mid \xi\right)
$$

We have

$$
\begin{aligned}
& \Gamma_{n} \equiv \Gamma_{n}(\xi) \Rightarrow \\
& \Gamma_{n}=\frac{d \Gamma_{n-1}(\xi)}{d h}=\frac{d \xi}{d h} \frac{d \Gamma_{n-1}(\xi)}{d \xi}
\end{aligned}
$$

where $h$ is conjugate to $\phi$.
From above

$$
\begin{aligned}
\Gamma_{n}(\xi) & =\int d^{D} \xi_{1} \ldots d^{D} \xi_{n-1} \xi^{(n-1) D-n \Delta_{\phi}} E\left(0, \xi_{1}, \ldots, \xi_{n-1}\right) \\
& =\xi^{(n-1) D-n \Delta_{\phi}} \cdot C_{n}
\end{aligned}
$$

where $C_{n}$ is a constant given by

$$
C_{n}=\int d^{D} \xi_{1} \ldots d^{D} \xi_{n-1} E\left(0, \xi_{1}, \ldots, \xi_{n-1}\right)
$$

Then from above

$$
\begin{aligned}
& \Gamma_{n}=\left[(n-2) D-(n-1) \Delta_{\phi}\right] C_{n-1} \xi^{(n-2) D-(n-1) \Delta_{\phi}-1} \frac{d \xi}{d h} \\
\Rightarrow & \frac{d \xi}{d h} \sim \xi^{D-\Delta_{\phi}-1} \\
\Rightarrow & \xi \sim h^{-\nu_{\phi}} \quad \text { where } \quad \nu_{\phi}=\frac{1}{D-\Delta_{\phi}} .
\end{aligned}
$$

Thus the critical exponent associated with the relevant external field $h$ conjugate to $\phi$, is given in terms of the scaling dimension of $\phi$, namely $\Delta_{\phi}$.

### 5.1 Scaling Relations

(1) From above the magnetic susceptibility satisfies the relation

$$
\chi \sim \xi^{D-2 \Delta_{\phi}} \sim t^{-\nu\left(D-2 \Delta_{\phi}\right)} .
$$

Since $\gamma$ is defined by $\chi \sim t^{-\gamma}$ we have the relation

$$
\nu D=\gamma+2 \nu \Delta_{\phi} .
$$

(2) It follows from scaling theory that

$$
M=<\phi>\sim \xi^{-\Delta_{\phi}} \sim t^{\nu \Delta_{\phi}} .
$$

Since $\beta$ is defined by $M \sim t^{\beta}$ we have that

$$
\beta=\nu \Delta_{\phi} .
$$

(3) $\beta(\equiv 1 / T)$ is conjugate to the energy operator $\epsilon(\mathbf{x})$ and hence

$$
\xi \sim t^{-\nu} \quad \text { with } \quad \nu=\frac{1}{D-\Delta_{\epsilon}} .
$$

Strictly speaking the only part of $\epsilon(\mathbf{x})$ that matters is the most singular, i.e., the component that has the lowest scaling dimension. In $\phi^{4}$ theory this is the operator $\phi^{2}$.
(4) The specific heat is

$$
C_{V}=T\left(\frac{\partial S}{\partial T}\right)_{V}=-T\left(\frac{\partial^{2} F}{\partial T^{2}}\right)_{V}
$$

with $F=-T \log \mathcal{Z}$. Thus

$$
\begin{aligned}
C_{V} & =\beta^{2} \frac{\partial^{2}}{\partial \beta^{2}} \log \mathcal{Z} \\
& =\beta^{2} \int d \mathbf{x}<\epsilon(0) \epsilon(\mathbf{x})>\quad \Rightarrow \\
C_{V} & \sim \xi^{D-2 \Delta_{\epsilon}}=t^{-\nu\left(D-2 \Delta_{\epsilon}\right)} .
\end{aligned}
$$

Since $\alpha$ in defined by $C_{V} \sim t^{-\alpha}$ we find

$$
\nu D=\alpha+2 \nu \Delta_{\epsilon} .
$$

(5) From above $M \sim \xi^{-\Delta_{\phi}}$ and $\xi \sim h^{-\frac{1}{D-\Delta_{\phi}}}$. Since $\delta$ is defined by $M \sim h^{\frac{1}{\delta}}$ we find

$$
\delta=\frac{D-\Delta_{\phi}}{\Delta_{\phi}} .
$$

Combining these relations we derive the scaling relations

$$
\begin{aligned}
\alpha+2 \beta+\gamma & =2 \\
\alpha+2 \beta \delta & =2+\gamma
\end{aligned}
$$

Note the following
(i) Only two relevant or unstable directions occur in $\phi^{4}$ field theory which correspond to $h$ and $T$ and are associated with the relevant operators $\phi$ and $\epsilon$ respectively.
(ii) All critical indices are controlled by $\Delta_{\phi}$ and $\Delta_{\epsilon}$ or equivalently by the dimensions assigned to $h$ and $T$

$$
[h]=D-\Delta_{\phi} \quad \text { and } \quad[T]=D-\Delta_{\epsilon} .
$$

The rest is dimensional analysis. Hence in this case there are only two independent indices.

### 5.2 Renormalized Green Functions

This is a very large topic since the ideas underlying the concept of renormalization and their impementation are central to the modern theory of analysing both quantum field theory and quantum and classical statistical mechanics. In this course we have time only to introduce the main ideas using the critical theory as the example, and to link these ideas with the notions which have gone before.
We work with a scalar field theories which lie in the critical surface $\left(\xi=\infty \quad \Rightarrow \quad m^{2}=0\right)$. Of course, the approach can be extended to study near critical theories and non-leading corrections to the predicted leading scaling behaviour.
Define $\Gamma_{n}\left(\mathbf{p}, \mathbf{g}_{0}, \Lambda\right)$ to be the 1PI truncated Green function. We will consider the effect of the "thinning" procedure but will not rescale the observable quantities. In other words we shall use the fact that the "thinning" procedure produces a new theory with the same low-energy predictions as the original one. The effect of "thinning" is encoded directly in the relation

$$
\Gamma_{n}\left(\mathbf{p}, \mathbf{g}_{0}, \Lambda\right)=Z^{-\frac{n}{2}}\left(\frac{\Lambda}{\mu}\right) \Gamma_{n}(\mathbf{p}, \mathbf{g}(\mu), \mu)
$$

$\mu$ is the new cut-off after thinning and the $\mathbf{g}(\mu)$ are dimensionsless couplings with $\mathrm{g}(\Lambda)=\mathrm{g}_{0}$.
The LHS is independent of $\mu$ and hence

$$
\left(\mu \frac{\partial}{\partial \mu}+\beta_{i}(\mathbf{g}) \frac{\partial}{\partial g_{i}}-\gamma^{\frac{n}{2}}(\mathbf{g})\right) \Gamma_{n}(\mathbf{p}, \mathbf{g}(\mu), \mu)=0
$$

where

$$
\begin{aligned}
\gamma(\mathbf{g}) & =\mu \frac{\partial}{\partial \mu} \log Z=\left(-\Lambda \frac{\partial}{\partial \Lambda}+\beta_{i}(\mathbf{g}) \frac{\partial}{\partial g_{i}}\right) \log Z \\
\beta_{i}(\mathbf{g}) & =\mu \frac{\partial}{\partial \mu} g_{i}(\mu) .
\end{aligned}
$$

This equation satisfied by $\Gamma_{n}$ is the renormalisation group equation. Note that

$$
\lim _{\Lambda \rightarrow \infty} \Gamma_{n}(\mathbf{p}, \mathbf{g}(\mu), \mu)=\lim _{\Lambda \rightarrow \infty} Z^{\frac{n}{2}}\left(\frac{\Lambda}{\mu}\right) \Gamma_{n}\left(\mathbf{p}, \mathbf{g}_{0}, \Lambda\right)
$$

is finite. $\Gamma_{n}(\mathbf{p}, \mathbf{g}(\mu), \mu)$ is the renormalized Green function.
Consider $\phi^{4}$ field theory.
(i) $\gamma(g)$

$$
\begin{aligned}
\frac{d}{d p^{2}} \Gamma_{2}\left(\mathbf{p}, g_{0}, \Lambda\right)_{\mathbf{p}^{2}=\mu^{2}} & =Z^{-1}\left(\frac{\Lambda}{\mu}\right) \frac{d}{d p^{2}} \Gamma_{2}(\mathbf{p}, g(\mu), \mu)_{\mathbf{p}^{2}=\mu^{2}} \\
& =Z^{-1}\left(\frac{\Lambda}{\mu}\right) f(g(\mu))
\end{aligned}
$$

$f(g)$ is a dimensionless function of $g$ and can be calculated in perturbation theory

$$
f(g)=1+a g^{2}+\ldots
$$

There are no divergences because $|\mathbf{p}|=\mu$, which is the cut-off. We also have (calculating in the limit $\epsilon \rightarrow 0$ )

$$
\frac{d}{d p^{2}} \Gamma_{2}\left(\mathbf{p}, g_{0}, \Lambda\right)_{\mathbf{p}^{2}=\mu^{2}}=1+g_{0}^{2} \log \left(\frac{\Lambda}{\mu}\right)+\ldots
$$

The corrections introduced by keeping $\epsilon$ finite in this calculation give rise to corrections to $\gamma$ which are higher order in $\epsilon$. Then from above we get

$$
\begin{aligned}
Z\left(\frac{\Lambda}{\mu}\right) & =\frac{1+a g^{2}(\mu)+\ldots}{1+\alpha g_{0}^{2} \log \left(\frac{\Lambda}{\mu}\right)+\ldots} \\
\Rightarrow \gamma & \equiv \mu \frac{\partial}{\partial \mu} \log Z \\
& =\alpha g_{0}^{2}+2 a g(\mu) \beta(g(\mu)) \ldots
\end{aligned}
$$

From the renormalization group equation $\gamma$ is a finite (i.e., $\Lambda$ independent) function of $g(\mu)$. This follows because both $\beta(g)$ and $\Gamma_{n}(\mathbf{p}, g(\mu), \mu)$ are independent of $\Lambda$ and the RG equation cannot balance unless $\gamma$ is independent of $\Lambda$ too.
Since $g_{0}=g(\mu)+O\left(g^{2}(\mu)\right)$ we can make the substitution for $g_{0}$ in terms of $g(\mu)$ and find

$$
\gamma(g)=\alpha g^{2}+2 a g \beta(g) \ldots
$$

(ii) $\beta(g)$

$$
\Gamma_{4}\left(\mathbf{p}, g_{0}, \Lambda\right)_{\mathbf{p}^{2}=\mu^{2}}=Z^{-2}\left(\frac{\Lambda}{\mu}\right) \Gamma_{4}(\mathbf{p}, g(\mu), \mu)_{\mathbf{p}^{2}=\mu^{2}}
$$

But

$$
\Gamma_{4}(\mathbf{p}, g(\mu), \mu)_{\mathbf{p}^{2}=\mu^{2}}=\mu^{\epsilon}\left(g(\mu)+b g^{2}(\mu)+\ldots\right),
$$

again a finite function: $b$ is an $\epsilon$-independent number. Note that $\Gamma_{4}$ has engineering or ordinary dimension $\epsilon:\left[\Gamma_{4}\right]=\epsilon$. These dimensions are carried by the $\mu^{\epsilon}$ factor.
We also have that

$$
\Gamma_{4}\left(\mathbf{p}, g_{0}, \Lambda\right)_{\mathbf{p}^{2}=\mu^{2}}=\Lambda^{\epsilon} g_{0}-\frac{\beta_{0}}{\epsilon} \Lambda^{2 \epsilon} \mu^{-\epsilon} g_{0}^{2}+\ldots
$$

To see how the form of the second term on the RHS arises we note that it comes from an integral of the form

$$
\text { Const. } \cdot \int_{\mu}^{\Lambda} \frac{d^{4-\epsilon}}{q^{4}} .
$$

Ignore the $\mu$-independent terms and terms that are not leading non-trivial order in $\epsilon$.
[We note in passing that the above equations show to lowest order that $g(\mu)=\left(\frac{\mu}{\Lambda}\right)^{\epsilon} g_{0}$. In the calculation for $\gamma$ we worked in the $\epsilon \rightarrow 0$ limit since we only required the leading order results in that case. This is why we were able to use $g_{0}=g(\mu)$ in that calculation. If we want to work to higher orders in $\epsilon$ we must be more careful.]
Then

$$
\mu^{\epsilon}\left(g(\mu)+b g^{2}(\mu)\right) \approx \Lambda^{\epsilon} g_{0}-\frac{\beta_{0}}{\epsilon} \Lambda^{2 \epsilon} \mu^{-\epsilon} g_{0}^{2},
$$

(Note that $Z=1$ to the order in which we are working.) Now apply the operator $\mu \frac{\partial}{\partial \mu}$ with $\beta=\mu \frac{\partial g(\mu)}{\partial \mu}$. We get

$$
\begin{aligned}
\epsilon\left(g+b g^{2}\right)+(\beta+2 b g \beta) & \approx \beta_{0}\left(\frac{\Lambda}{\mu}\right)^{2 \epsilon} g_{0}^{2} \\
& =\beta_{0} g^{2}+\ldots
\end{aligned}
$$

where the expression for $g_{0}$ in terms of $g$ has been used in the last step. Hence

$$
\beta \approx \frac{-\epsilon g+\left(\beta_{0}-\epsilon b\right) g^{2}}{1+2 b g}
$$

Keeping only non-trivial orders in $\epsilon,\left(\beta_{0}\right.$ is $\left.O(1)\right)$ gives

$$
\beta=-\epsilon g+\beta_{0} g^{2}+\ldots
$$

We have already computed $\beta_{0}$ before when calculating the critical exponent $\nu$ (note that when comparing these two calculations we must remember that $d \log \mu=-d b$. This accounts for the sign difference between the two otherwise identical versions of the flow equation). For $\mu \ll \Lambda$ we find $g(\mu)=g^{*}$ where

$$
\beta\left(g^{*}\right)=0 \quad \Rightarrow \quad g^{*}=\frac{\epsilon}{\beta_{0}}
$$

and we found before that $g^{*}=\frac{16 \pi^{2}}{3} \epsilon$.
A consequence of the two calculations above is that for $\mu \ll \Lambda$ we have

$$
\frac{d}{d \log \mu} Z\left(\frac{\Lambda}{\mu}\right)=\gamma(g(\mu))=\gamma\left(g^{*}\right)
$$

Or, writing $\lambda=\frac{\mu}{\Lambda}$

$$
Z=Z_{0} \lambda^{\gamma\left(g^{*}\right)}
$$

But from the scaling analysis near the fixed point

$$
Z \sim \lambda^{2 \eta_{\phi}} .
$$

Thus

$$
\begin{aligned}
\eta_{\phi} & =\frac{1}{2} \gamma\left(g^{*}\right) \\
\Delta_{\phi} & =\left(\frac{D}{2}-1\right)+\frac{1}{2} \gamma\left(g^{*}\right)
\end{aligned}
$$

From (i) above $\eta_{\phi}=\frac{1}{2} \alpha g^{* 2}$ since $\beta\left(g^{*}\right)=0$.
We now indicate how to calculate $\alpha . \Gamma_{2}$ is given by the graphs

$$
\begin{aligned}
& \left(\frac{-1}{p}\right)^{-1}+\underset{p}{ }+\cdots+ \\
& \mathbf{p}^{2} \quad+\quad C \Lambda^{2} g_{0}^{2}+\quad\left(g_{0}^{2} D \Lambda^{2}+\alpha \mathbf{p}^{2}\right) \log \frac{\Lambda}{\mu} \quad+\ldots
\end{aligned}
$$

The calculation of $\alpha$ is somewhat involved and will not be reproduced here. From Raymomd's book "A Modern Primer on Field Theory" we find

$$
\begin{aligned}
\alpha & =\frac{1}{6\left(16 \pi^{2}\right)^{2}} \\
\Rightarrow & \\
\eta_{\phi} & =\frac{1}{2} \frac{1}{6\left(16 \pi^{2}\right)^{2}}\left(\frac{16 \pi^{2}}{3}\right) \epsilon^{2} \\
& =\frac{1}{108} \epsilon^{2} .
\end{aligned}
$$

What happened to all the couplings corresponding to the irrelevant operators (i.e., those with dimension $\Delta>D$ )? A calculation of the $\beta$ functions for these operators in the same way as in (ii) above shows that the fixed point for these couplings is at the origin. This is expected because
(i) the operators corresponding to these couplings do not give rise to extra IR diverrgences: $D>D_{c}$ for these operators. This implies that Landau's approach works and the critical exponents receive no anomalous contributions from these operators.
(ii) mean field theory works for operators whose associated couplings have their fixed point at the origin.

$$
\eta_{\phi}=\frac{1}{2} \gamma\left(\mathbf{g}^{*}\right),
$$

but only $g^{*}$, the $\phi^{4}$ coupling, is non-zero.
(iii) The corollary is that only the renormalizable operators in the usual sense, i.e. $\Delta<D$ are relevant since only their couplings flow to IR stable fixed points which are not at the origin. For those operators with $\Delta=D$ the fixed point is at the origin but we find log, rather than power-law, corrections to mean field theory. These operators constitute a special case but an important one since, for example, scaling violations in Quantum Chromodynamics are exactly of this kind.
